[a] No fires.

Final fire statistics for 1907 for national forests (area approximately 150,000,000 acres).

[Compiled from supervisors' annual fire reports by E. A. Ziegler.]

1. Total area burned over, 212,850 [a] acres, or 0.14 per cent of 150,000,000 acres reporting.
2. Timbered area burned over, 29,365 [b] acres, 0.0002, or less than 0.007 per cent of the 450,000,000,000 feet board measure, estimated stand, on this area.
3. Amount of timber destroyed, 31,026,000 board feet.
4. Value of timber destroyed, $31,590.
5. Cost of fire fighting (exclusive of forest officers' salaries):

Labor	$4,259
Supplies	718
Total	4,977

6. Total number of fires reported:

Class A	845
Class B	280
Class C	181
Unclassified	49
Total	1,355

7. Causes of fires:

Campers	346
Railroad locomotives	273
Lightning	176

---

[a] Large area burned over due to three large grass fires on Dismal River (Nebr.) national forest, 51,200 acres; Garden City (Kans.) national forest, 38,400 acres; Wichita (Okla.) national forest, 13,840 acres; total, 103,440 acres.

[b] Includes area of 11,500 acres in Chiricahua national forest, Arizona, reported as timber land, but only 100 board feet per acre were destroyed.

7. Causes of fires—Continued.

Donkey engines	65
Clearing land	34
Incendiary	19
Hunters	9
Herders	6
Miscellaneous	60
Unknown or not reported	367

The Forest Service may justly pride itself upon this showing. The amount of hardship and self-sacrifice undergone by forest officers in order to achieve these results will never be known. The point is that rangers are stationed at convenient intervals throughout the entire forest area; that by their enforcement of the laws and regulations fires are for the most part prevented, but that when fires do occur they are discovered promptly and the necessary steps taken to extinguish them. Rangers are authorized to hire help and fight fire and to purchase necessary provisions. Rangers in adjoining districts and supervisors in adjoining forests cooperate with each other to prevent and control fire, and no effort is spared to prevent the destruction of the forest from this cause. The results already accomplished have clearly demonstrated the fact that destruction of forest property by fire may be almost entirely prevented by the adoption of a suitable system of patrol.

Probably the best example of cooperation betweeen the Federal Government, the State, and the counties in the prevention and control of forest fires occurs in southern California. Under the terms of the state forest law enacted in 1905 the state forester is authorized to maintain a fire patrol in times and localities of particular fire danger. Firewardens are appointed by the state forester, but their salaries and the cost of patrol must be met by the counties in which the patrol is maintained. The greatest danger from fire to the national forests in southern California is from the foothill region along the west boundary, outside the present limits of the forests. In the past these areas have in general been unprotected and great damage from fire has resulted, not only to the areas outside the forests, but to the forests themselves, from fires originating on the outside and burning across the forest boundary. During the past two years, however, a plan has been adopted for the cooperative patrol of a considerable portion of these foothill regions. The plan has been for the Forest Service and the county to provide an equal number of men for this patrol during the four months of greatest fire danger. The firewardens to be paid by the counties are appointed by the state forester. Under the law these appointments may be made, where required by public interests, whether the county concurs or not. In a number of cases the initiative has been taken by the state forester in this way with excellent results. The adoption of this plan has brought about a notable decrease in the number and severity of fires in the foothill region of southern California. Much also has been accomplished in the way of enforcing state fire laws by the general appointment of forest rangers as state firewardens.

Until the past year but little had been accomplished by the Federal Government in the way of cooperation with railroad companies for the prevention of fires on the national forests. That railroad locomotives have been one of the greatest menaces to the forest is unquestionable. That this is true has for the most part been due to two facts: (1) The absence or defective condition of spark arresters; and (2) the failure of the companies to take proper precautions against the spread of fire through the clearing of rights of way and the issuance to employees of proper instructions with regard to the control of such fires as are set by locomotives.

The first deficiency is gradually being remedied through the enforcement of state laws. With regard to the second, practically no steps have been taken outside the national forests, and there only during the past year, after the initiative had been taken by the Forest Service.

At the end of the calendar year 1907, 32 of the national forests in the United States were traversed by coal or wood-burning locomotives through timbered areas in which the railroad rights of way were in such a condition that effective measures were necessary for the protection of the forests from fire. To meet this need the matter was systematically taken up by the Forest Service and an attempt made to secure cooperative agreements with each of the roads operating in the 32 forests mentioned. Field examinations of the rights of way have been made by forest officers, and these reports have formed the basis of action. The details of cooperative agreements are being discussed with a number of railroads. Where cooperation can not be secured it is the policy of the service to sue the railroads for civil damages in every case where damage to the national forest occurs from fire due to the negligence or disobedience of law on the part of any railroad company.

The principal features of the proposed cooperative agreement are as follows:

1. The railroad company agrees to cut and remove all live and dead timber from a strip 250 feet in width on each side of the roadbed on all vacant government land and all lands owned by the company which are crossed by the roadbed within the exterior boundaries of the national forest, the work of clearing this strip to commence not later than a specified date and to be continued, until completed, with reasonable diligence.

2. The railroad company further agrees to clear such strips of all young growth, brush, and other inflammable material, and at all times during the life of the agreement to keep such strips clear of all inflammable material. The cutting of the timber and the clearing of the strips to be done at all times under the direction and to the satisfaction of the supervisor of the national forest in question.

3. The forester authorizes and permits the railroad company to enter upon such portions of said strips as lie upon vacant government land within the national forest, and to remove all live and dead timber and to appropriate the same without charge for the use or benefit of the railroad company.

4. The railroad company permits the forester to attach such telephone lines as may be needed for the proper protection of the national forest to telegraph or telephone poles of the railroad company along the right of way within or near the boundaries of the national forest, such attachments to be made in accordance with the instructions of the railroad company.

5. The railroad company agrees to adopt a system of notifying the forest officers of any fires discovered by train crews or other employes of the railroad company by warning whistles and by telegraph or telephone communication, such system to be approved by the officer in charge of the forest.

6. The railroad company agrees to furnish at all times at the request of any authorized forest officer a sufficient number of men to assist in fighting fire on or near the right of way, together with necessary tools and the subsistence required while so employed.

7. The forester further agrees to patrol the right of way of said railroad company, and so far as possible to aid in extinguishing fires on or near the right of way.

8. The forester further agrees to supervise the cutting of the timber and clearing of the strips before mentioned, provided that proper and necessary assistance is furnished by the railroad company.

9. The forester further agrees to construct and maintain sufficient telephone lines and to supply at proper points tools and other necessary equipment, sufficient for the effective fighting of fires on or near the right of way.

A good example of actual cooperation on the part of a railroad company occurred during the past summer. The Chicago, Milwaukee and St. Paul Railway Company is constructing a transcontinental railroad through the Cœur d'Alene National Forest, Idaho. Their right of way within the forest is 28 miles in length. Several thousand foreigners are employed upon this work, and during the season the danger from fire along the right of way was very great. An understanding was reached with this company this summer through which it cooperated with the Forest Service by establishing a fire-patrol force of 80 men along the right of way. These men were under the control of four civil engineers, who, before the fire season, had been engaged in construction work on the railroad. It was provided that these men, although in the pay of the railroad company, should be subject to the orders of the forest rangers in that district. As may be expected, a large number of forest fires originated from stragglers from the construction camps, and probably in some cases through the direct carelessness of the contractors and others engaged in construction work on the railroad. These fires were in every case attacked by the patrol force of the railroad and the rangers and were controlled and extinguished before any great damage was done. Had officers of this forest not been successful in securing the cooperation of the railroad company in this region it is probable that the extensive virgin stand of white-pine timber through which the railroad passes would have been completely destroyed.

(b) RESULTS ACCOMPLISHED ON MILITARY RESERVATIONS, NATIONAL PARKS, AND INDIAN RESERVATIONS.

On the military reservations there is very little destruction of timber by fire. The reservations are for the most part small and the proportion of commercial forest low. It is estimated that on all the military reservations there are but 72,964 acres of commercial forest. The estimated total stand of timber is 307,063,000 feet board measure. The presence of troops on or near each reservation makes it possible to extinguish promptly any fire that may occur. In some cases patrol is maintained to guard against forest fires. The timbered portion of the Fort Grant Military Reservation, Ariz., has been included in the Crook National Forest, and protection from fire is secured through the patrol maintained by the Forest Service. The same action has been taken with regard to the Fort D. A. Russell Wood and Timber Reserve, Wyo., now a part of the Cheyenne National Forest. The War Department reserves the right to make use of these areas for military purposes, but the grazing and timber and other business and the protection of these areas from fire are conducted by the Forest Service exactly the same as on other national forest land.

The efficiency of the methods adopted by the War Department for the protection of military reservations from damage by forest fires is shown by the following table. Only such reservations are listed as are reported to contain merchantable timber. The figures are from statements made by the respective officers in charge:

Name of reservation.	Area of reservation. Acres.	Area burned in 1907.	Method of prevention and control.
Arizona:			
Fort Grant	42,000	None	Forest Service cooperation.
Fort Huachuca	44,800	do.	Use of troops.
Florida:			
Fort Barrancas	2,700	do.	No steps necessary.
Cedar Keys	211	do.	Do.
St. Johns Bluff	117	do.	Do.
Georgia and Tennessee:			
Chickamauga and Chattanooga	6,362	do.	None.
Georgia:			
Fort McPherson Rifle Range	1,271	do.	Do.
Point Peter	1,100	do.	Do.
Illinois:			
Rock Island Arsenal	1,000	do.	Fire service.
Indiana:			
Fort Benjamin Harrison	1,997	do.	Daily observations.
Kansas:			
Fort Leavenworth	6,970	1,000 acres ($500)	Forester, range riders, daily patrol.
Maine:			
Fort Knox	124	None	Patrol in dry season.
Fort Levett	125	do.	Troops available.
Montana:			
Fort Missoula Wood and Timber Reservation.	1,577	do.	Occasional patrol from post 6 miles distant.
Fort Assinniboine	168,610	do.	Troops available.
New Mexico:			
Fort Bayard	13,780	do.	Judicious grazing.
New York:			
Fort Wadsworth	230	do.	Fire department.
West Point	2,556	do.	
North Carolina:			
Fort Caswell	2,325	do.	None.
Oregon:			
Fort Stevens	1,250	do.	Supervision of garrison.
South Dakota:			
Fort Meade	7,700	150 acres ($50)	Guard duty.
Virginia:			
Fort Hunt	197	None	Burning grass in fall.
Washington:			
Three Tree Point	640	do.	None.
Hoods Head	43	do.	Do.
Gig Harbor	78	do.	Do.
Port Defiance	638	do.	Guard by employees.
Nee-ah Harbor—			
West side	381	do.	None.
East side	398	do.	Do.
Washington Harbor—			
West side	475	do.	Guard by lessee.
East side	424	do.	None.
Challam Point	548	do.	Do.
Hope Island	200	do.	Guard by lessee.
Northern part of Whidby Island.	606	do.	None.

Name of reservation.	Area of reservation.	Area burned in 1907.	Method of prevention and control.
Washington—Continued.			
Deception Pass—	*Acres.*		
South side	630	None	None.
North side	550	do	Do.
Shaw Island	1,103	do	Guard by residents.
Lopez Island	1,311	do	Do.
San Juan Island	1,124	do	Do.
Fort Townsend	615	do	Guard by caretaker.
Tala Point	102	do	None.
Foulweather Point	485	do	Do.
Double Bluff	626	250 acres ($3,000)	Do.
Vashon Island	487	None	Do.
Protection Island (land opposite).	254	do	Do.
Fort George Wright	1,023	do	Patrol by soldiers.
Fort Ward	230	do	
Fort Flagler	906	do	Cleared strip.
Wyoming:			
Fort D. A. Russell Target and Maneuver Reservation.	36,800	do	Notices, Forest Service patrol.

On the national parks protection from fire is as complete as on the military reservations, according to the reports of the respective superintendents. The parks are in general much larger than reservations and contain a much greater area of merchantable forest. It is estimated that in all the national parks there are 2,540,000 acres of merchantable forest. The total stand of timber on this area is estimated at 10,717,000,000 feet b. m. Where danger from fire exists a regular patrol is maintained, and a sufficient body of troops is available to promptly extinguish any fire that may occur.

The following table shows results obtained along this line during 1907 on such national parks as are reported to contain merchantable timber. The figures are from statements submitted by the respective superintendents:

Name of park.	Area of park.	Area burned in 1907.	Methods of prevention and control.
California:	*Acres.*		
Yosemite	967,680	None	Guard by cavalry.
Sequoia and General Grant	172,165	do	Patrol, warning notices, road, trail, telephone, fire lines, tool stations.
Oregon:			
Crater Lake	159,360	do	Patrol.
Pennsylvania:			
Gettysburg	2,047	do	Guards, workmen, and tenants.
Tennessee:			
Shiloh	3,325	do	Annual ground fires.
Washington:			
Mount Rainier	207,360	do	Regular fire patrol (3 men during July, August, and September), 2 tool stations, warning notices.
Wyoming:			
Yellowstone	2,142,000	do	Daily patrol, troops and rangers, enforcement of park regulations, fire-fighting tools constantly accessible.

No statistics are available as to damage by forest fires on the Indian reservations. It is, however, known that these reservations have received immense damage from year to year, and that but little effort has been made to prevent the indefinite recurrence of such damage. Fires occurring near the agencies have in many cases been extinguished. No provision has, however, been made by Congress for a systematic patrol. Superintendents of Indian reservations have neither the authority nor the funds to employ men for fire fighting, and it is very difficult to get the Indians to voluntarily perform work of this kind. Under such circumstances, fires will inevitably occur in the future, as they have in the past, in the more remote and inaccessible regions. These fires usually owe their origin to carelessness, malice, or natural causes, and, as a rule, continue unchecked until they either burn out or are extinguished by rain.

Indian reservations are located in 14 States and Territories. It is estimated that there are in all the reservations 10,541,900 acres of merchantable forest, carrying a stand of 34,089,000,000 feet b. m. of timber. That adequate steps should be taken for the safeguarding and perpetuation of this vast property can not now be questioned. Undoubtedly a comprehensive system of protection and management should be adopted, based upon that now in use upon the national forests. A beginning along this line has already been accomplished by the cooperation of the Forest Service with the Indian Office during the past summer. On the Klamath and Coeur d'Alene Indian reservations the plan is in actual operation and will be carried on indefinitely so long as funds are available. Its extension to other forests is merely a matter of time.

The total area of the Klamath Indian Reservation, Oreg., is about 1,100,000 acres; of this, it is estimated that 700,000 acres are timbered. The question of cooperative protection arose during the summer of 1908, the Indian agent being unable to cope successfully with the several large fires which were burning on the reservation. After some correspondence, an understanding with the Indian Office was reached whereby 5 men were placed on patrol on the reservation under the direction of the supervisor of the Crater National Forest, whose headquarters are at Medford, Oreg. A fund of $2,500 was made available in the Indian Office to cover the salaries of these men during the fire season. An additional sum of $1,000 was made available to be expended by the Indian agent for fighting fire. Owing to the fact that several fires had gained great headway before steps were taken toward their extinguishment, the entire balance of the fire season was spent in fire fighting, with the result that the fires were brought under control and a vast amount of timber saved from destruction.

A similar plan was put into effect during the past summer on the Coeur d'Alene Indian Reservation in northern Idaho. This action was made necessary by the fact that two lines of railroad cross the reservation, thus endangering not only the timber on the Indian land, but also on the adjacent Coeur d'Alene National Forest. As in the case of the Klamath Reservation, a plan was adopted whereby three forest guards were placed on patrol under the direction of the supervisor of the Coeur d'Alene National Forest. Just as this plan was approved, occasion arose to test it through a severe fire on the Indian reservation.

On August 5 and 6 a forest ranger who was patrolling a district in the Coeur d'Alene National Forest some distance south of the Coeur d'Alene Indian Reservation, noticed considerable smoke drifting in from the country to the north of the national forest. On the 7th the smoke became so dense that the ranger left his district and traveled on horseback into the Indian reservation, where he discovered a large forest fire burning in valuable timber on the reservation. The reservation authorities at this time had no system of fire protection on their lands and nothing was being done to check the fire. The flames had a front of about 5 miles and were traveling rapidly before a strong wind through a dense forest of white and yellow pine, red fir, hemlock, and tamarack. Nearly a half-billion feet of merchantable timber was in imminent danger. Officers of this forest at that time had no authority to fight fires on the Indian reservation. The ranger, however, rightly judged that some action could be taken to save the government's property, and rode to St. Maries, the nearest telephone office. Upon telephoning to the supervisor of the national forest at Wallace, he was instructed to take in a crew of 20 men to the fire and return to St. Maries for instructions.

Meanwhile the forester was wired from Wallace that forest rangers were fighting fires on the Indian reservations, and instructions were requested. On August 8 the forester replied by wire, instructing the officers of this forest to extinguish the fire and to keep him informed by telegraph.

About 40 more men were accordingly gathered and dispatched to the fire, which was located in an inaccessible region. In order to get in camps and supplies for this large crew, it was necessary to construct several miles of trail, and the entire force was put on the fire within twenty-four hours after receiving final instructions from the supervisor at Wallace, and within another twenty-four hours the fire was practically under control.

The burned area was large and was covered with smoldering logs, stubs, and remnants of the fire. It was not possible to extinguish the fire within the burned area, and the efforts of the men were directed toward hastily constructing a trail or fire line around it and fighting the fire back on this line. For several days strong winds prevailed, and it was only by the greatest effort that the men were able to hold the fire within the burned limits. In some instances the fire leaped the barriers and more fire lines had to be constructed around newly burned areas.

The weather continued exceedingly dry, and it was nearly four weeks before it was possible to withdraw all the men. As this district was remote from the supervisor's office at Wallace, and the supervisor himself was constantly engaged in controlling the many fires on the national forest, it was difficult to provide means for promptly paying the men. Most of them were hastily secured from many sources and were penniless. In order to retain them it became necessary to devise means for promptly paying them for their services. Firewarden Ross of the State and Lumberman's Protective Association, who was stationed at St. Maries, volunteered to reimburse the men through orders drawn on the association, the account of the association to be, of course, later submitted to the Government for payment.

The cost of fighting this fire was approximately $4,500, of which nearly one-fourth was expended in supplies and equipment, the remainder being paid in wages.

Probably one-half billion feet of timber, valued at $2,000,000, were saved by controlling this fire. The great cost of fighting this fire is in contrast to those extinguished on the Coeur d'Alene National Forest, the average cost of which amounted to about $400 per fire. The difference is due entirely to the fact that there is on the Coeur d'Alene National Forest a system of fire patrol and protection, and fires in the forest were discovered and extinguished before they gained much headway. It is probable that at a cost not exceeding $2,000 a system of fire patrol could have been maintained on the Indian reservation which would have prevented the great damage done by this fire.

(c) RESULTS ACCOMPLISHED ON THE PUBLIC DOMAIN.

Of the unappropriated public domain outside of Alaska it is estimated that 4,448,400 acres are forest land, bearing a stand of 13,838,000,000 feet b. m. of timber. This area is so widely scattered, and is passing out of the hands of the Government at such a rapid rate, that its protection and administration would be impracticable even were there any provision for such a course. As a matter of fact, there are neither funds nor men available for this purpose, and absolutely no steps have been or are being taken to prevent the destruction by fire of timber on the public domain. In the States of Oregon, Washington, Idaho, Montana, Wyoming, and Colorado further additions to the National Forests are prohibited by law, except by act of Congress. Important bodies of commercial forest in the other States have either been included in National Forests, or are under temporary withdrawal, or else have been filed upon and are either patented or in process of becoming so. Under these conditions but little action on the part of the Federal Government is practicable along the line of fire protection. In some cases fires on the public domain adjacent to the National Forests are extinguished by forest rangers. This action is taken in every possible case where the National Forest is threatened. Owing, however, to the limited amount of money available for fire protection on the forests, but little protection to lands outside can be given by the Forest Service.

The unappropriated timber lands of the public domain are for the most part either in such small bodies or are situated so remotely from transportation that they offer but little attraction to the individual as an investment. In many cases they consist of isolated and widely scattered tracts of 40 or 80 acres, so that it is impracticable to secure a satisfactory timber and stone claim; in others the amount of timber on a possible claim is so small that it is not worth while to go to the expense of locating and filing; and in many instances the timber is so far distant from possible transportation or utilization that its location is not considered good business policy. It must be realized, also, that only a small percentage of the remaining public domain contains commercial forest, and that great expense and loss of time are involved in determining from the land office records what areas are still unappropriated and in making the necessary field examinations to ascertain which of these areas are timbered. These conditions are for the most part responsible for the fact that any of the timbered portion of the public domain still remains in the hands of the Government.

Not only is the timbered portion of the public domain rapidly passing into private ownership, but the danger from fire to the portion remaining is constantly increasing. The comparatively small isolated tracts are for the most part surrounded by private holdings of timber lands. Some of these lands have already been lumbered and others are being held for future cutting. On the lands which have not been lumbered there has until very recently been practically no attempt at fire protection. The lands of the public domain have received the same damage from fire that has been received by lands in private ownership. Where, however, privately owned lands have been lumbered the slash has been left on the ground, forming a fire trap, and the resulting damage from fire to adjacent uncut timber on the public domain has been very great. As lumbering proceeds on private holdings the damage to unreserved government timber lands will constantly increase, until practically all the timber on the public domain is either filed on or destroyed by fire.

(2) RESULTS ACCOMPLISHED BY STATE GOVERNMENTS.

As compared with the urgent need for adequate prevention and control of forest fires but little has been accomplished by state action. Many laws have been passed by the various States, which vary greatly among themselves, and many look well upon the statute books. Laws against the setting of fires are far from uniform, but in practically all cases they would be sufficient were they enforced. The fact is, however, that they are not enforced, and never have been in any State. The machinery for proper enforcement is wanting. If the owner or his agents catches a man setting a fire he can prosecute through the proper office, bring the case into court, and if he can get the jury to convict he can get the offender punished. It is, however, a matter between owner and court, and not one of proper police. This lack of protection has in general worked strongly against the holding of forest lands as a permanent investment. In many parts of the country areas that would otherwise have been held for future cutting or for a second crop have been cut clean because of the fear that if this action were not taken great loss would result from forest fires. Small areas of timber surrounded by cut-over lands have been considered as practically doomed and every effort made to get them lumbered before their destruction by fire.

Usually with the first code adopted by each State came laws (derived like the laws on forest trespass) dealing with the prevention of fires in forest and on prairies. Like the laws on trespass, these earlier efforts are simple, direct, and severe. Thus in Michigan as early as 1846 the law provided a penalty for willfully burning the woods of another amounting to as much as five years in State prison and a fine of $500. Quite early, and in some cases as parts of the first protective act, came provisions making the fighting of forest fires a special duty of the supervisor, the justice of the peace, or the highway commissioner or some other official, giving these officials power to call out the citizens and making it obligatory, under severe penalty upon the citizen, to obey summons and help in the fight against fire. The responsibility of the local authorities was thus clearly recognized at an early date. But there was a penalty prescribed only for the citizen and not for the officer, and so the officer found it to his political interest never to call people out.

Thus these laws (even more than the laws of trespass) remained dead letters. The difficulty of catching the evil doer, the ease of finding excuses in having to clear land, burn brush, cook food on camp fire, etc., and thus establishing some reason for the existence of fire; then, also, the matter of accident, the pipe, the cigar and match and torch all allowed in the forest at any time and season; the general permission of any one to travel, camp, hunt, and fish on other people's lands; all these made it practically impossible for the owner or his agent to bring the matter before court and secure conviction. And even if conviction could be had, it could have been of little value, for it is prevention of fire and not merely conviction of the "fire bug" that is wanted. And here, again, State, county, and town did nothing; and with this the sense of individual as well as corporate responsibility disappeared.

After a number of really great calamities, like the fires of 1871, 1881, and 1894 in the Great Lakes region, where hundreds lost their lives, thousands became homeless, and the damage ran well up in the millions, the situation became positively intolerable. The people clamored for action and the legislatures reluctantly enacted a series of laws, all of which were more or less modifications of the old fire-fighting laws already in existence, and collectively perhaps best termed "firewarden" laws. Like the trespass agents and game-warden laws, they are a makeshift, a duplication and interference in what should and could be the proper administrative body of the state government. The Michigan law, copied and modified from that of New York and Minnesota and again copied by Louisiana, etc., will illustrate this phase of state action. The State had a good, simple, though somewhat incomplete, forest-fire law, with a provision which made it the duty of the supervisor, justice, and road commissioner to call out the people and fight forest fires. Beyond this the State never spent a cent in protecting its second greatest natural resource and its second industry.

After enormous losses and years of agitation, the legislature, in 1903, made the state land commissioner a state forest commissioner (and this in spite of the fact that he already was a member of the state forestry commission), gave him power to appoint a state fire-warden. This man, with a salary of $500 per year, had authority over the supervisors, who were thus once more legislated into the fire-warden job. The earlier law was repeated in its main features, but the people were to receive pay for fighting fires, and the sum total spent in any one town should not exceed $50 in any one year, so that if $49 were once spent the people had to be sent home because there was no more money available. The state land commissioner himself in a public meeting declared that the law was not worth the paper it was printed on.

In 1907 the power of the land commissioner was transferred to the state gamewarden, who was made fire and game warden; the idea being, since this office was equipped by law with deputies scattered over the State, that it was a mere police body and thus would do better work. The fact is, however, that the law has fallen far short of accomplishing the desired end. During the past season (1908) fires have raged throughout the northern peninsula of Michigan and throughout the northern portion of southern peninsula. Although every supervisor was by law compelled to fight forest fires, as a rule no steps were taken until some town or especially valuable piece of private property was threatened with flames. In many cases action of this kind was taken too late, and as a result, in the State of

Michigan alone, loss was caused amounting to several million dollars. The same thing has been true in Wisconsin and Minnesota and many other States during the present season. In no State is there as yet an adequate system of protection against forest fires. Some of them have, however, been far more progressive than others and have made good beginnings along this line. The figures already quoted as to fire losses in some of the States, while neither complete nor accurate, are sufficient to demonstrate that even small expenditures of money and effort are well repaid by the results obtained. The difficulty has benn that in every case the expenditures of money and effort have been inadequate to meet the real needs of the situation.

The results of the forest-fire law in New Jersey illustrate to a remarkable degree the great saving brought about by protective measures. The law creating the forest park reservation commission was passed in 1905. A state forester is employed by the commission to superintend the general forest work. In 1906 provision was made for a state forest-fire service, under the direction of a state firewarden. The essential feature distinguishing the New Jersey plan from that adopted in other States is a paid organization which ignores property lines, covering the whole State and cooperating in every way possible with the owners of woodland, with the railroads, and with everyone having an interest in the suppression of fires. Township wardens receive $20 and district wardens $10 per year in addition to a per diem compensation for the time actually spent in fire fighting. The service now includes 300 firewardens, all of whom are expected to be on the lookout for fires and to summon help to extinguish one the moment it is discovered.

For this purpose they are authorized to require the services of any able-bodied citizen, under a penalty of $10. The expense of fighting fires is borne equally by the townships and State. The report of the state firewarden shows that for the year 1907 the loss from forest fires was less than one-tenth of that of any former year. This betterment in conditions can be traced directly to the activity of the firewardens. An important feature in this connection is the issuing of permits for burning brush. During the entire year no fallows, stumps, logs, brush, dry grass, or fallen timber may be burned in specified townships without the written permission of a firewarden. Such permission is refused where the burning would endanger any forest or woodland. In the past the burning of brush for the clearing of land has been the most fruitful source of forest fires. As a result of the new law, it is significant that but 7 per cent of the forest fires reported in 1907, whose origin is known, started from brush fires, whereas in former years the proposition was usually about one-fourth to one-third. The success of the state forest policy has been reflected in a general rise in the value of forest land. Rough woodland worth less than $1 an acre a few years ago is now held at $5 and more. Undoubtedly a part of this increase has been due to the general rise in land values, but there is no question but that the additional security from loss by fire under the new law has been an important factor in bringing about a realization of the revenue-producing possibilities of forest land.

New York is another good example of a State with fire laws which are progressive as compared with those of the great majority of the States. Even in New York, however, the law is inadequate to meet the situation. It is believed that the figures given in the first part of this paper for fire losses in the Adirondack and Catskill counties do not represent even approximately the true loss, to say nothing of the entire State. Much as has already been done, more remains to be accomplished, and unquestionably the facts justify the statement made by Col. W. F. Fox, superintendent of state forests, that without the system of state protection at present in force, fires would have been unchecked and would have resulted in the destruction of the entire forest. The state law provides for the appointment by the forest, fish, and game commissioner of a chief firewarden, to have supervision of town firewardens, visit and instruct them in their duties, and enforce the law as to fire districts in towns, and under the authority of the commissioner commence prosecutions for violations of law, to prevent forest fires. The law provides also for the appointment by the commissioner of a firewarden in every town having lands in the forest preserve, and the optional appointment of a firewarden in every town having lands that would become a part of the forest preserve if acquired by the State. Division of towns into two or more fire districts is provided for, to be guarded by district firewardens appointed by the town firewardens. In towns not included in the forest preserve the supervisor is made firewarden by virtue of his office. Firewardens, district firewardens, and laborers receive pay for time actually employed in fire fighting. All bills are approved by the firewarden and paid by the town in which the fire occurs. When approved by the commissioner one-half the amount is reimbursed the town by the State. During the present year there are 743 town and district firewardens under appointment.

The law provides also that whenever in the judgment of the commissioner it is necessary to protect the forests from fire he shall organize and, as long as necessary, maintain a fire patrol along the lines of railroad in forests in counties containing part of the forest preserve, and at such other places in such counties as the public interest requires, one-half the expense to be borne by the company and one-half by the State.

In order to reduce as much as possible the danger from railroads, each railroad company is required by law, on such part of its road as passes through forest lands or lands subject to fires from any causes, to cut and remove from its right of way along such lands, at least twice a year, all grass, brush, and other inflammable material. Patrol of tracks at the expense of the company is required, as is also the use of efficient spark arresters. Were these laws fully enforced immense good would result. That the desired protection has not yet been secured is shown by the fact that during the present season fires have raged all through the Adirondack and Catskill regions, it being claimed by the state authorities that 90 per cent of the fires have been caused by railroads. The State spent over $100,000 in fighting fire this year, but more than 1½ millions of dollars worth of property has nevertheless been destroyed. What is needed is the inclusion of further immense areas of nonagricultural forest lands in the state preserve, and the adoption of an adequate system of fire patrol at the expense and under the supervision of the State. The action most needed, however, is a law that will compel the adoption of electricity or oil as motive power for railroad locomotives through forest regions. The numerous disastrous fires that have occurred during the summer of 1908 have made this a distinct issue in New York, and the question is under investigation by the public service commission. Hearings have already been held, at which were present representatives of the railroad companies, as well as of a number of private and public interests and organizations desirous of securing adequate protection from forest fires.

As an argument in favor of the compulsory adoption of petroleum as fuel, the case is cited of the Raquette Lake Railway, which extends for 19 miles through the state forest from Clearwater to Durant. In granting the charter for this road the legislature stipulated that petroleum must be used for fuel. During the twenty years that this road has been in operation not a single fire has occurred along its right of way. The agitation for the general adoption of petroleum as fuel is met by the railroads with the statement that the Adirondack and Catskill roads are neither strong nor profitable, and that the expense of equipping the locomotives with oil burners would be almost confiscatory. It is contended also that many of the fires attributed to the railroads have in reality been set by the indiscriminate building of small fires for camping and pleasure purposes. The fact that some of the railroads in the Western States are changing from steam to electric power, utilizing local water powers for this purpose, was cited as an argument in favor of similar action in New York. This, however, was met by the contention that it would be impracticable to operate the roads by electricity secured from water power in the Adirondacks, as these water powers are insufficient during the dry season when railroad traffic is heaviest.

Along with New York and New Jersey, the States of Pennsylvania, Minnesota, Wisconsin, Maine, Maryland, Connecticut, Washington, and California are generally regarded as having done most to secure protection from forest fires. There is great variation as to the details of the plans in operation, the idea being generally adhered to, however, of firewardens under State supervision, paid locally, or in part locally and in part by the State. In general the same conditions prevail as have already been described for Michigan and New York with regard to the nonenforcement of laws and inadequacy of measures adopted.

In Maine, the legislature each year makes provision for the expenditure of $20,000, or so much thereof as may be necessary, to be used in fire fighting. In dry years this amount is absolutely inadequate, and the burden falls on the individual owners. In a number of cases fire-lookout stations are erected and equipped by the owners of wild lands, the State paying in each case the salary of the men assigned to the station, the owners bearing all other expenses. These stations are located on mountains commanding views for long distances, and are equipped with telephones and fire-fighting tools. Lookouts are maintained from June to November.

In Connecticut a firewarden system was provided by law in 1905. The state forester is ex officio forest firewarden without additional salary. About 400 wardens are under appointment, and the annual fire damage has been reduced to about one-fourth what it was before the adoption of the fire law.

In Wisconsin the state forester acts also as state firewarden, with power to appoint one or more firewardens in each town. Over 300 of these wardens are now under appointment in the northern part of the State. The State has also appointed an inspector, whose duty it is to examine all railroad locomotives in use in the northern part of the State, to see that they carry efficient spark arresters, and that the rights of way of the railroads are kept free from grass, brush, and other inflammable material.

Minnesota is one of the pioneers with regard to forest-fire protection. Supervisors of towns, mayors of cities, and presidents of village councils are ex officio firewardens under the direction of the chief firewarden, who is appointed by the forest commissioner. Five thousand dollars may be expended for fire fighting. Gen. C. C. Andrews, who as chief firewarden has been in charge of this work for many years, reports that the measures adopted have lessened the fire damage very greatly.

The Washington legislature enacted a forest-protection law in 1905. This law provides for the appointment by the governor of a state board of forest commissioners to serve without compensation. This board has power to appoint firewardens in each of the timbered counties of the State. While the measures taken have been effective in preventing fire damage to some extent, yet the number of wardens appointed (22 in 1905 and 23 in 1906) has been insufficient to meet to any degree the real needs of the situation. Outside the National Forests, fires have for the most part occurred on cut-over lands. This has given rise to an attempt to minimize the damage by fires which have occurred during the present season. In making estimates of such loss, however, little attention has been paid to the medium-sized material destroyed and none to the young growth. Almost invariably fires on cut-over lands encroach on virgin timber, and in the heavy forests of the Northwest the loss mounts up with great rapidity. Instead of spending $4,300, as in 1905, and $5,190, as in 1906, the State could well afford to appropriate such amount (between $25,000 and $100,000 annually) as would provide for an efficient patrol and make forest fires a thing of the past. As it is, the work of protection is, as a matter of fact, left to the individual owners to provide for.

In California the forest-fire situation is anything but satisfactory. One-third of the State, or approximately 33,000,000 acres, is in some degree forested, of which 25,000,000 acres are in the national forests. This leaves 8,000,000 acres of forest land for the protection of which the State is properly responsible, in addition to an immense area of chaparral, brush, and grass land, on which there is constant danger from fire during the dry season of the year. The only exception to this is perhaps in the redwood belt of Mendocino, Humboldt, and Del Norte counties, where, on account of the prevalence of summer fogs, fires do practically no damage over an extent of 1,000,000 acres. The greatest damage from fire is in the southern part of the State, along the foothill ranges, outside the National Forests. In the northern part much of the finest timber is in the hands of individuals and private corporations, and is situated outside the National Forests. But little protection from fire is furnished by lumbermen, and still less by the State. The annual loss from forest fires occurring outside the National Forests is upward of half a million dollars, according to the estimate of the state forester. There is great variation from year to year, the estimate for 1890 being upward of ten millions for the entire State, according to the report of the state board of forestry for 1889–90.

A voluntary firewarden system is in operation, appointments being made by the state forester. About 700 wardens have been appointed, who are given power under their appointments to arrest for violations of the forest laws, to issue burning permits (without which it is unlawful to set any except camp fires during a dry season), and to compel assistance in fighting fires. Because the State made no appropriation from which firewardens could be paid for their services, the preventive value of the system has not been great. To increase it, many counties have been requested to make appropriations, as allowed under the state law, from which firewardens acting within the county could be paid. This has resulted in the appropriation of money in the following counties to support the number of firewardens indicated:

Santa Cruz.—One firewarden.

Los Angeles.—One firewarden, and funds from which fire fighters are paid for their services.

San Bernardino.—Five hundred dollars from which firewardens are paid for their services.

Riverside.—Five hundred dollars from which firewardens are paid for their services.

Tulare.—Two hundred and fifty dollars for payment of firewardens.

San Diego.—Five hundred dollars for payment of firewardens.

Fresno.—Two regular firewardens and $500 for payment of services rendered by fire fighters.

Kern.—One thousand two hundred and fifty dollars for two regular firewardens and services rendered by fire fighters.

Merced.—One regular firewarden.

Glenn.—One regular firewarden.

Madera.—Two firewardens.

Santa Clara.—One firewarden.

In general, the best results from state efforts and the only ones which have been quite satisfactory have been derived from the action of several of the States in establishing state forests or parks. First in the list come New York, Pennsylvania, and Wisconsin; then the smaller beginnings made in Minnesota, Michigan, Connecticut, Massachusetts, New Jersey, Indiana, etc. The New York state forest preserve comprises 1,599,638 acres; the area of the Pennsylvania state reserve is 761,000 acres; and in Wisconsin 300,000 acres have been set aside as a state reserve, including 20,000 acres donated by the Federal Government. The area of lands reserved for forest purposes in some of the other States is as follows: Michigan, 39,000 acres; Minnesota, 42,800 acres; New Jersey, 9,867 acres; California, 3,800 acres; Indiana, 2,000 acres; Maryland, 1,957 acres; and Connecticut, 1,600 acres. Protection from fire is an important part of the system of management which it is expected will be inaugurated on these lands as rapidly as funds will permit. Judging from the example set by the most progressive states of continental Europe, the segregation, protection, and management of the state forests will ultimately become the principal line of state activity with regard to forest matters in this country. The conditions in Michigan are a good illustration of the desirability of such action on a large scale in States where there are cut-over forest lands not chiefly valuable for agriculture. Michigan owns at the present time about 800,000 acres, most of which has reverted to the State for nonpayment of taxes. These lands are in general not valuable for agricultural purposes.

They have cost the State millions of dollars in advertising and clerk hire; they have been sold over and over again at purely nominal prices without an investigation as to their value. The lands which the State now owns have been cut over repeatedly; immense areas come up every year for nonpayment of taxes; and still the State spends large sums trying to get rid of them. During the past five years Michigan has sold over 800,000 acres of tax lands at about $1.20 per acre. It is now shown by special examinations that they had timber enough on them to pay the above sum twice over. Thus the State has given away land and timber and young trees to the amount of millions of dollars. Not only that, but the lands thus sold are held by the owners just long enough to cut off the timber; the land then burns over, and the tract again reverts to the State for nonpayment of taxes. Thus the land policy pursued by this State has robbed the State of millions of money and of millions of acres, and directly resulted in the total and repeated devastation of immense areas of land chiefly valuable for the production of timber. Had the State kept its lands, sold them only on application and at fair price, and separated all poor lands as forest reserves, it would have received more money, these reserves would now produce an income instead of causing expense, fires would be done away with, and the State of Michigan would be in a fair way to supply itself again with all forms of timber instead of having to import them, as it now does. What is true of Michigan in this regard is true also of many other States. Where lands do not revert to the State for nonpayment of taxes, a policy of purchase, protection, and reforestation is the only practicable solution of the present unsatisfactory condition.

In addition to this policy, however, which can at the best be carried on but slowly, and which should include only lands not chiefly valuable for agriculture, the States should immediately take radical action to provide an efficient patrol for all forest regions. The many fires which have occurred during the present season in all parts of the United States emphasize this need with greater strength than has been the case in any previous year. In this connection the following quotation from The Minnesota Forester for September, 1908, is of interest as an illustration of conditions in the Northwest:

> On September 1, 1894, the forest fires swept over that portion of the State surrounding Hinckley. They wiped out that town completely, damaged several other towns, burned over 400 people, left over 2,000 others homeless, and destroyed property valued at $25,000,000. Investigations showed that the loss was the result of carelessness in regard to forest fires in their incipiency. It was shown that a reasonable amount of money expended by the State in patrol and other preventive measures would preclude any such disasters in the future.
>
> Under pressure of public opinion and the findings in regard to the cause of the loss the legislature grudgingly appropriated $6,500 for forest protection, $1,500 to be paid to a chief forest firewarden. The legislature seemed to feel that it had met the requirements, but it had totally ignored the "reasonable amount."
>
> Fourteen years later (1908) another fire wipes another town (Chisholm) off the map, damages others, leaves thousands of persons homeless, and destroys $5,000,000 worth of property. Investigation shows that the fire was caused by carelessness and neglect in fighting fire when it was small.
>
> The direct and immediate loss from these two conflagrations was about $30,000,000. The consequent loss of wealth production in the following years would probably amount to more than that, but is ignored in these calculations, because few people look deep enough to see it. The direct losses, then, from these two fires would pay the state appropriation for fire protection, as it now stands, for the next 4,600 years. Is that not rather a low insurance rate,

especially when it is remembered that these two fires form only a fraction of the total losses to the State? The forestry commissioner has at his disposal about a quarter of a mill an acre for the protection of the land under his care. No business concern in the world would expect to get adequate protection at such ridiculously low rates.

An appropriation of half a cent an acre on the 20,000,000 acres of forest land would furnish efficient protection. That would mean an appropriation of $100,000 per year. It sounds like a great deal of money. The losses sustained in the Hinckley and Chisholm fires alone would pay it for 300 years. Considering that 20,000,000 acres are worth only $3 per acre—the value of all the towns in the district ought rightly to be figured in—we have a property worth $60,000,000. One hundred thousand dollars premium on even such a valuation would be less than 1½ mills on the dollar. What kind of insurance can be obtained for less?

It is to be hoped that the disasters in the neighborhood of Chisholm will awaken the state legislature to the ridiculous business methods which they have been using in the administration of their northern forests and impress upon them the necessity of larger appropriations to prevent such disasters in the future. The landowners in the forested districts pay taxes and should get protection; they get nothing else for their taxes and should insist on having the protection.

(3) RESULTS ACCOMPLISHED BY PRIVATE OWNERS.

In reply to questions sent out by the National Conservation Commission to owners of large tracts of forest lands throughout the United States, replies were received from 369 individuals or firms, representing holdings amounting to 13,150,085 acres. Of this area it was reported that 3,917,087 acres are protected from fire. This, however, does not mean that on this area the prevention of forest fires is secured, but that while prevention is secured in some cases, in general an organized attempt is made to extinguish such fires as may occur.

It is estimated that of the 450,000,000 acres of forest land in private ownership in the United States, probably not more than 1 per cent is under an efficient system of fire protection. By an efficient system is meant one in which prevention is the object sought rather than merely control after fires have actually begun. As already stated, for a system of this kind some plan of patrol is essential. A few years ago practically no attention was paid to forest fires by lumbermen and private owners, loss from this source being considered inevitable and pertaining naturally to the business. With the depletion of the timber supply, however, and the rapid rise in stumpage prices, a gradual change has taken place. Individual owners have been more ready to spend money to protect their holdings; cooperation has gradually developed in cases where fire danger is greatest, and in some instances, as in Idaho and in Washington, the movement for concerted action has spread until it has covered the largest timber interests of the respective States, involving even the State and Federal Governments in the general plan. The steps so far taken have been confessedly inadequate, since they have for the most part fallen far short of preventing fire damage. They are, however, moves in the right direction, and the results obtained show conclusively that fire damage can be practically eliminated provided the owners of forest property affected are willing to pay a reasonable amount for the protection. Money spent in this way is the cheapest possible form of insurance and is repaid many times over, not only in the form of the timber saved but in the higher values resulting from greater security from loss.

The Pocono Protective Fire Association is a good example of what can be accomplished in the way of preventing damage by forest fires through the cooperation of private owners. This association is an organization of forest owners in northeastern Pennsylvania, whose property aggregates upward of 100,000 acres. To stop the fires that have burned over their land every year the association began five years ago by securing the appointment of deputy constables in each of the seven townships in which its members own forest. Under the state law these men have all the powers of firewardens, including authority to call on any citizen to assist in fighting fire. A reward of $100 is offered for information leading to the arrest and conviction of any person starting a fire, or for such information as could be used as evidence against railroad companies. The expenses are met by an annual assessment of 6 mills per acre of land owned by the members. As a result strict enforcement of existing laws has been secured, and damage by forest fires has been practically eliminated on the tract in question.

The experiment conducted on the cut-over land of the McCloud River Lumber Company, in northern California, is a good example of what may be accomplished in the way of fire protection on forest lands in private ownership. This experiment was started in 1905, in accordance with a plan prepared by the Forest Service. The tract had been logged for the seven preceding years, and about 43,000 acres cut over. The amount of combustible débris left on the ground as a result of the lumbering operation was very great. Young growth existed in great quantities and of all sizes up to 18 inches in diameter. The problem was to adopt an adequate system of fire protection in order that the small and medium sized trees might reach merchantable size and at the same time the surrounding timber forest be protected from the menace incident to the proximity of so large an area of cut-over land. In accordance with the plan prescribed, fire lines were constructed at an average cost of $15 per mile. A patrol route was laid out, covered by a mounted patrolman daily for the four months of greatest fire danger—that is, from June to September. Tool stations were located at convenient points and telephone lines so constructed as to make it possible for the patrolmen to secure help quickly in case of fire. The total cost of protection for the area under patrol was 2 cents per acre, which included the initial cost for fire lines, tool stations, etc. As a result of the first year's work, the loss by fire was practically nothing, the few fires which really started having been speedily discovered by the patrolmen and extinguished without assistance.

In view of the success of the plan during the first year it was extended during 1906 to cover all the holdings of the company. These holdings are extensive and fairly well consolidated, and it will take a considerable time to cut over the present virgin stand. More important than this is the topographic character of the tract, which renders logging both easy and cheap. This, perhaps more than any other one thing, justifies the leaving of trees for a future cut, since the comparatively level nature of the country will make it possible to return again and log profitably, even where the stand per acre is relatively small. The cheapness of the protection secured on the McCloud tract and its thorough efficiency should serve as an object lesson to other owners of forest lands.

During the past year an efficient organization of lumbermen in northern Idaho has been formed, cooperating with the State, and known as the State and Lumbermen's Protective Association. The object is the prevention and control of forest fires on lands outside the national forests under private, corporative, and state ownership. Under the state law, wardens and deputies are appointed upon whom police powers are conferred. A paid patrol is maintained, and where necessary, temporary laborers are employed for fire fighting, the expense being apportioned among the respective owners and the State in proportion to the acreage of holdings involved. A complete system of trails has been outlined and work begun in many places. The patrolmen employed by the association are chosen on the basis of merit and their familiarity with the region in which they are to work. As a result of the adoption of the plan, a feeling of mutual interest has grown up between the State, lumber companies, individual owners of timber land, settlers, and all who are desirous of preventing and suppressing fires. There has also been cordial cooperation between the association and the Forest Service. Fires outside the national forests but near their boundaries were discovered by rangers of the Forest Service, who promptly notified the proper officials of the association. During this time the officers of the association were having their hands more than full with forest fires all over northern Idaho. In some instances the officers of the Protective Association were unable to handle the fires reported to them by the rangers, and in these cases the rangers, acting under the authority of the association, secured men and supplies and extinguished the fires, the expense of same being met by the association. In other instances the association put men and supplies at the disposal of the forest officers in fighting fires within the boundaries of the national forest.

On the Pacific coast the best example of cooperation among private owners is the Washington Fire Association, with headquarters at Seattle. This organization was effected early in 1908. It was incorporated under the laws of Washington "for the preservation of the forests of the State of Washington generally, and particularly from loss by forest fires, and the enlistment of the aid of the United States of America and the State of Washington in preserving said forests and preventing their destruction by fire."

The membership of the association includes 138 of the largest owners of timber lands in the Northwest, representing holdings aggregating 2,600,000 acres, 75 per cent of which is held by 8 or 10 companies. An assessment of 1 cent per acre for the season was levied. The amount thus secured was sufficient to carry the operations through the season, but had early rains not occurred, an additional levy of at least one-half cent per acre would have been necessary, as the fires were becoming larger and harder to handle. The timber companies were compelled to organize for protection, since the $7,500 appropriated by the legislature was sufficient only to maintain the office of the state firewarden and forester ~~and~~ to pay the salaries and expenses of the deputy firewardens in the different counties.

The administrative work of the association is conducted by the chief firewarden. During the season of 1908 the association had 75 men in the field from June 15 to September 15. These men were appointed forest rangers at large under the provisions of the state law, which gives authority to make arrests without warrant of persons violating the fire law. The State was divided into districts, each man covering approximately four townships. Seven inspectors were appointed, each one having charge of from 7 to 12 rangers. Weekly reports were required and suitable equipment furnished, consisting of ax, hoe, and water bag. In addition, tools, such as shovels, mattocks, saws, and buckets, were stored at convenient places. Most of the men were mounted on horses, some used wheels, and a few went on foot, owing to the country being too rough to permit the use of a horse. Every man was instructed to notify the deputy firewarden in the county and also the chief firewarden at Seattle by telephone or telegraph in case of a serious fire.

Most of the fires occurred during July and August, and the great majority were started from railroad locomotives and donkey engines. During these months the rangers extinguished 838 camp and other small fires covering not more than a few square rods; 162 small forest fires extinguished without any extra help or expense, generally not covering more than 5 acres; and 102 large fires, requiring extra help and expense; total, 1,102 fires. There were 18,773 acres of land burned over, of which 743 acres were timbered; of this it is estimated by the chief firewarden, Mr. D. P. Simons, jr., that one-half was damaged. There were employed 607 men, the total amount spent for fire fighting amounting to about $4,000, in addition to the salaries of the men under appointment. While excellent work was accomplished, considering the newness of the work and the number of men available, there is no question but that, as stated by Chief Firewarden Simons, twice the number of men actually employed should have been on duty.

In addition to the patrol and fire-fighting work, great good was accomplished by the forest rangers in inspecting logging locomotives and donkey engines and sawmills located in forest regions, and enforcing the law requiring efficient spark arresters. Companies operating logging locomotives, donkey engines, or mills not so equipped were allowed five days in which to comply with the law, and the request of the chief firewarden along this line was in every instance met by prompt compliance on the part of the company concerned.

It has been impossible to secure similar cooperation on the part of the railroads, according to Chief Firewarden Simons. The companies all claim to have a screen set diagonally in front of the tubes. This, however, is almost never kept in proper repair, owing to its serious interference with the steaming power of the locomotive. The coal used is of a poor grade and clogs the screens, so that the engineer usually opens the front and punches the screen full of holes. Mr. Simons believes that until a better grade of coal is used on the coast, or oil burners are adopted, there will always be trouble with forest fires caused by the railroads. An attempt was made by the association to induce the railroads to put on track patrolmen, but the only concession secured was the assurance that the section crews would assist in case of fires along the right of way.

Mr. Simons favors the appropriation by the State of $125,000 per year for fire protection. This would provide a sufficient field force to see that slashings are burned at the proper time, thus reducing the fire risk to a minimum. The cooperative establishment of telephone lines to reach inaccessible regions is another measure favored by the association which would aid greatly in securing proper fire protection.

In Wisconsin steps have been taken looking to the formation of associations for the prevention and control of forest fires similar to those in Idaho and Washington. The initiative has been taken by the state forester. The plan is to appoint patrols, to be employed during the dry season, the expense to be apportioned among the owners interested in proportion to the areas of their holdings. These patrols, when employed, would be appointed firewardens under authority of state law, and would receive every possible assistance and cooperation on the part of the state forester and other state officials.

In Connecticut the various water companies are especially active in fire prevention. Most of them have their superintendents appointed district firewardens. In the town of Simsbury the New York, New Haven and Hartford Railroad Company has cooperated with the authorities in establishing a fire patrol during April and May. The railroad company pays one-half of this expense, the town a portion, and the adjoining landowners the remainder. Some 40 fires were this year extinguished by this patrol, which would otherwise have burned over a large area that has been annually burned.

The Pennsylvania Railroad Company, operating in the eastern portion of the United States, has made some progress along the lines of fire protection. The problem is confined mainly to the prevention of fires on timber lands or wood lots owned or controlled by the company and along rights of way where injury to adjoining property might result in damage suits. On a watershed property of about 9,000 acres a firewarden has been employed during the spring and fall seasons for the past two years, who has patrolled the track and reported to the Altoona office any fires which he could not control. The results have been very satisfactory and no serious damages have occurred. In addition to the patrol, notices have been posted on several tracts calling attention to the danger from fire, and requesting the assistance and cooperation of all campers, berry pickers, etc. As a general measure of protection, and one which has proved very efficient, all employees in divisions which run through forested or brush lands are instructed at the beginning of the spring fire season to keep a look out for fires, extinguish those which they are able to reach and control, and report all others to division headquarters. These orders apply to trackmen, and as a result of the vigilance of a large number of men, fires have little opportunity to get beyond control before being reported. Probably the most dangerous region, from the standpoint of fires started from locomotive sparks, is in the southern part of New Jersey. Here, for many miles along the Cape May division and on the Newfield branch, a strip 100 feet wide on each side of the track is cut clean and burned over once or twice a year. On the outside of the strip furrows are plowed to prevent grass fires which start near the track from running into adjacent woodlands. The difficulty in this kind of protection is that the landowners frequently object to having such a strip cleared, and through the popular desire to hold up the railroads, the tendency is to charge a rental which makes such work prohibitive. Nevertheless, much good has been accomplished in the shape of fire prevention in this way.

In the South the best example of fire protection is the Pisgah forest, owned by the Vanderbilt estate, with headquarters at Biltmore, N. C.

This forest has an area of 130,000 acres, and has been under conservative forest management during the past twelve years. Protection against fire was the most serious problem which had to be met during the first years of management. The general policy has been to enforce strictly the fire and stock laws of the region, while at the same time cultivating in every possible way the friendship and good will of the native population and educating them to respect owners' rights and to see that the prevention of forest fires and of unrestricted grazing is for the best interests of the country as a whole. This policy has secured excellent results. Infractions of the fire and stock laws have been followed up vigorously as far as evidence could be obtained, as well as ordinary trespass, poaching, and theft of timber. The estate during the first few years experienced a great deal of trouble in these respects, with damage suits on hand much of the time. Within the last few years, however, trouble of this sort has greatly decreased. Moreover, the careful system of protection established on the tract has had a moral influence upon the native population. On the greater part the rangers claim that practically no spring fires are now started intentionally, and that there is very little trouble with the stock. The rangers keep on good terms with the natives as far as possible and show them the evil effects of fire and heavy grazing and the objects of the protective system on the estate.

This method has proved very successful, and as a result the local mountaineers have largely discontinued the practice of firing their own lands to improve grazing. Protection against fire is the principal duty of the head rangers. The ranges are marked out in regular sections across the tract, each including a portion of the high mountains on the Pisgah Range. On each range a number of elevated peaks have been selected from which practically the entire area can be clearly seen and fires readily detected. During any time of drought and fire danger these points are patrolled constantly, in some cases day and night, by assistant rangers, who are nearly always tenants on the tract. The main mountain patrol is usually made by men in pairs. When a fire is discovered one of these men hastens to it with all available help. The other hunts up and informs the head ranger and then collects a crew of fire fighters from the tenants on the range. The tenants, moreover, form a fire-fighting staff, loyal to the estate, equipped with saddle horses, and thoroughly acquainted with the region. They can be called upon at any time to fight the larger fires or to do special patrol work. A permanent staff of this kind makes the estate independent of outside help and avoids the danger of outsiders starting fires in the hope of securing employment. Between the tenants and the regular rangers, fires are usually quickly detected and extinguished. The roads and trails form a good network of fire lines, and are furthermore of the utmost value in protection, because they furnish rapid communication between all parts of the tract.

When a fire has not yet gained much headway, or is burning against the wind, or when the woods are comparatively moist and not burning readily, or the fire as usual in the fall is confined to the leaves, the men form a line and beat it out directly with hemlock boughs, sacks, or bunches of hard-wood twigs.

When the fire is well under way, especially if the woods are dry and burning fiercely, with a good deal of combustible material on the ground, or if the fire is running with the wind, the men begin at once to back fire. They usually work in crews of eight. Two men go ahead with pitchforks, clearing a strip about 5 feet wide of combustible material. Two others follow with rakes, completing the clearing of the strip by raking off the leaves and smaller twigs. Care is taken to direct the line well away from down timber or logs and dead stubs or stumps which might enable the back fire to jump the trail. Two more men follow, firing the leaves on the side of the strip toward the blaze, the rest of the crew spreading out along the strip at close intervals to see that the fire does not jump the cleared path. The lane and back fire can in this way be run very rapidly, often at the rate of a mile or a mile and a half an hour.

The system of protection used on this tract, while expensive, appears to be very effective. The aim is to keep out fire at any cost. No risk is taken that can be avoided at reasonable expense, under the general plan of spending money to keep out fire rather than in fighting fire after it once gets in. In this way thoroughgoing protection has been secured, though at an annual cost of probably 4 cents an acre.

CONCLUSION.

The direct loss to the United States each year from forest fires is not less than $50,000,000. The indirect losses are beyond calculation, but are certainly several times as great as the direct loss. Experience both in Europe and the United States shows conclusively that loss from forest fires is practically preventable at reasonable expense. Except on the National Forests and in a few isolated instances the measures adopted are totally inadequate to meet the needs of the situation. What is needed is a general realization by the public of these facts, followed by the improvement and enforcement of existing laws and the expenditures of adequate sums of money as a business measure, not only by the Federal Government but by the States and by corporations and private owners of forest lands. Further delay is business folly as well as a national calamity.

WASTE AND REDUCTION OF TIMBER SUPPLIES CAUSED BY INSECTS, AND METHODS OF PREVENTION AND CONTROL.

By A. D. Hopkins,
In Charge of Forest Insect Investigations, Bureau of Entomology.

CHARACTER AND EXTENT OF DEPREDATION.

The records of notable depredations by insects on the timber supply of Europe during the past four hundred years, and on that of the United States during the past century, and especially those that have come under the observation of the writer and his assistants during the past eighteen years, furnish conclusive evidence that this class of enemies has been, and is now, an important factor in the destruction and waste of forest resources.

CAUSE OF THE DEATH OF TIMBER.

It has been determined that in this country certain species of insects are the direct or primary cause of the death of trees of all ages, and that from time to time they multiply to such an extent as to take the character of a destructive invasion, resulting in the death of a large proportion of the timber of certain species over many square miles.

Examples.

The southern pine beetle.—A destructive invasion by the southern pine beetle (*Dendroctonus frontalis* Zimm.) in 1890–1892 extended from the western border of West Virginia through Maryland and Virginia into the District of Columbia, northward into southern Pennsylvania, and southward into North Carolina. In this area, aggregating over 75,000 square miles, a large percentage of the mature and small trees of the various species of pine and spruce was killed by this beetle. In certain localities in West Virginia and Virginia nearly all the pine trees of all sizes were killed on thousands of

---

[Note.—The statements and estimates in this report are based largely on observations and the results of investigations by the writer and his assistants, and information secured through correspondence with forest officials and private owners of timber and manufacturing enterprises. Much of it has been published in the various bulletins and circulars of the Bureau of Entomology, the West Virginia Agricultural Experiment Stations, and in proceedings of societies, etc., but there is also much original matter drawn from the unpublished notes and records of the Branch of Forest Insect Investigations of the Bureau and from the unrecorded experience and observations of the writer. Some of the statements and estimates may seem to be overdrawn or exaggerated, but they are based on available evidences and facts which indicate to the writer that they are conservative.—A. D. Hopkins.]

acres, while shade and ornamental trees within the same area suffered the same as those in the forest. It has been more or less active in the States south of Virginia to Texas since 1902, and in some localities and during some years it has killed a large amount of timber. Records of extensive dying of timber in the Southern States are found dating back to the early part of the nineteenth century. Therefore, this species may be considered as one of the most dangerous enemies and a constant menace to the pine forests of the Southern States.

The eastern spruce beetle.—During the period between 1818 and 1900 there were a number of outbreaks of the eastern spruce beetle (*Dendroctonus piceaperda* Hopk.) in the spruce forests of New England and southeastern Canada. It caused the death of a large percentage of the matured spruce over many square miles. The larger areas of this dead timber evidently furnished fuel for devastating forest fires, with the result that in most cases there was a total loss.

The Engelmann spruce beetle.—Another bark beetle of the same genus, and with similar habits, has from time to time during the past fifty years caused widespread devastations in the forests of Engelmann spruce of the Rocky Mountain region, in some sections killing as high as 90 per cent of the merchantable sized timber.

The Black Hills beetle.—One of the most striking examples of the destructive powers of an insect enemy of forest trees is found in the Black Hills National Forest of South Dakota, where during the past ten years a large percentage of the merchantable timber of the entire forest has been killed by the Black Hills beetle (*Dendroctonus ponderosæ* Hopk.). It is estimated that a considerable part of the total stand of timber has died in this forest as the direct result of the work of this beetle. This destructive enemy of the western yellow pine is distributed through the forests of the middle and southern Rocky Mountain region, in which it has been found that within recent years a large amount of timber has been killed by it, not scatteringly through the forests of the entire region, but here and there areas of greater or less extent where from 10 to 80 per cent of the trees have been killed by it.

The mountain pine beetle and western pine beetle.—The sugar pine, silver pine, western yellow pine, and the lodgepole pine of the region north of Colorado and Utah, westward to the Cascades and southward through the Sierra Nevada, are attacked by the mountain pine beetle (*Dendroctonus monticolæ* Hopk.) and the western pine beetle (*Dendroctonus brevicomis* Lec.), and, as a direct consequence, billions of feet of timber have died. In one locality investigated in northeastern Oregon it is estimated that 90 to 95 per cent of the timber in a dense stand of lodgepole pine, covering an area of 100,000 acres, has been killed within the past three years by the mountain pine beetle. Throughout the sugar-pine districts of Oregon and California a considerable percentage of the largest and best trees are dead as the result of attacks by this same destructive bark beetle.

The Douglas fir beetle.—The Douglas fir throughout the Rocky Mountain region from southern New Mexico to British Columbia has suffered severely from the ravages of the Douglas fir beetle (*Dendroctonus pseudotsugæ* Hopk.) resulting in a large percentage of dead timber, much of which will be a total loss.

Three other species of beetles of destructive habits, similar to those mentioned, depredate on the pines of New Mexico and Arizona, and still another has contributed greatly to the destruction of the eastern larch throughout the northeastern United States and southeastern Canada.

The hickory barkbeetle.—Within the past ten years the hickory barkbeetle (*Scolytus quadrispinosus* Say) has been the cause of the death of an enormous amount of hickory timber throughout the northern tier of States from Wisconsin to Vermont and southward through the eastern Atlantic States and into the Southern States as far as central Georgia.

The larch worm.—There are many examples of widespread depredations by insects which defoliate the trees and thus contribute to their destruction. Notably among these is the larch worm (*Nematus erichsonii* Hartig), which, during a number of extensive outbreaks since 1880, has killed from 50 to 100 per cent of the matured larch over vast areas in the northeastern United States and southeastern Canada. It is believed that the amount of merchantable sized timber that has died as a result of defoliation by this insect will aggregate many billions of feet.

INJURIES TO THE WOOD OF LIVING TREES.

It has been determined that a certain class of insects attack the wood and bark of living timber and that while they do not contribute materially to the death of the trees or show much external evidence of their presence, they cause wounds in the bark and wormhole and pinhole defects in the wood that often result in reductions in value amounting to from 5 to 50 per cent. The defects in the wood are not detected until after the trees are felled and the logs are transported to the mill and converted into lumber. Thus to the actual damage to the wood is added the expense of logging and manufacture of the defective low-grade material, much of which is discarded as worthless culls.

EXAMPLES.

The oak timber worm.—One of the most destructive of this class of depredators is the oak timber worm (*Eupsalis minuta*). It enters the trunks of living trees through wounds in the bark and at the base of broken or dead branches and extends its "pinhole" burrows in all directions through the solid heartwood. The losses occasioned by this insect in the hard-wood forests of the eastern United States are enormous and usually affect the finest examples of old trees.

The chestnut timber worm.—The chestnut throughout its range is damaged in a like manner by the chestnut timber worm (*Lymexylon sericeum*). Practically every tree of merchantable size is more or less affected and a large percentage are so seriously damaged that the product is reduced to the lowest grade. It is estimated that reduction in value of the average lumber product at any given time is not far from 30 per cent, thus involving extensive waste and an increased drain on the forest to supply the requirements for clear lumber. This insect also attacks the oaks, and especially the red oak, the older trees of which are often as seriously damaged as the chestnut.

The carpenter worm.—The oaks, especially the white oak and red oak, are seriously damaged by carpenter worms of the genus *Prionoxystus*. The holes made by them through the heartwood of the best part of the trunks are sometimes one and one-half inches in diameter one way by three-fourths of an inch the other, thus causing serious damage to the wood. These, with other large wood-boring grubs of beetles, sometimes infest the top part of the trunk and larger branches where their continued work results, first, in the dead and so-called "stag-horn" top and, subsequently, in broken, decayed, and worthless trunks.

The columbian timber beetle.—One of the most common defects in white oak, rock oak, beech, whitewood or yellow poplar, elm, etc., is that known to the lumber trade as "grease spots," "patch worm," and black holes. This is caused by one of the timber beetles or ambrosia beetles (*Corthylus columbianus* Hopk.) which makes successive attacks in the living healthy sapwood from the time the trees are 20 or 30 years old until they reach the maximum age. Thus the black hole and stained wood defect is scattered all through the wood of the best part of the trunks of the trees. The average reduction in value of otherwise best grade of timber in many localities amounts to from 25 to 75 per cent. The defect is commonly found in oak and elm furniture and in interior hard-wood finish in dwellings and other buildings.

The locust borer.—The locust, as is well known, suffers to such an extent from the ravages of the locust borer (*Cyllene robiniae*) that in many localities the trees are rendered worthless for commercial purposes or are reduced in value below the point of profitable growth as a forest tree; otherwise this would be one of the most profitable trees in the natural forest or artificial plantation and would contribute greatly to an increased timber supply.

The turpentine beetle and turpentine borer.—While the soft wood or coniferous trees suffer far less than the hard woods from the class of enemies which cause defects in the living timber, there are a few notable examples of serious damage. There is a common trouble affecting the various species of pine throughout the country known as basal wounds or basal fire wounds. It has been found that a large percentage of this injury to the pine in the States north and west of the Gulf and the Middle and South Atlantic States is caused by the dark red turpentine beetle (*Dendroctonus valens* Lec.), and in the Southern States by the black turpentine beetle (*Dendroctonus terebrans* Oliv.). These beetles attack the healthy living bark at and toward the base of the trunks of medium to large-sized trees and kill areas varying from 1 to 10 square feet. This is subsequently burned off by surface fires and is then generally referred to as fire wounds. The further damage to the exposed wood by successive fires, decay, and secondary insects often results in a total loss of the best part of the tree, or a reduction in values of from 10 to 50 per cent of the lower section of the trunk. These and similar wounds in the bark of trees, including those caused by lightning and by the exposure of the wood in turpentining, offer favorable conditions for the attack of the turpentine borer (*Buprestis apricans*). The work of this insect and two or three others with similar habits is very extensive and causes losses amounting to 10 to 50 per cent of the wood of the best part of the trees thus affected.

The white pine weevil.—The abnormal development of white pine trees as the result of successive attacks on the terminals of saplings and young trees by the white pine weevil (*Pissodes strobi* Peck) is an element of loss of considerable importance, especially in mixed stands and in open pure stands of this timber. The value of such trees is reduced 20 to 50 per cent, and there is an additional loss from the effect of their spreading branches or crowns in the suppression or crowding out of trees which would otherwise occupy the space thus usurped.

There are many other examples of damage by insects to the wood and bark of living trees, but those mentioned should be sufficient to demonstrate the importance of insects in their relation to injuries to the wood and growth of living timber.

INJURY TO THE WOOD OF DYING, AND DEAD TREES.

Timber dying and killed by insects and other causes, including fire, disease, storm, etc., is attacked by a class of wood-boring insects which extend their burrows through the sound sapwood and heartwood and thus contribute to the rapid deterioration and decay of a class of resource which otherwise would be available for utilization during periods of from one to twenty years or more after the death of the trees, depending on the species of trees and character of product desired. This loss often amounts to from 25 to 100 per cent during the period in which the dead timber would otherwise be almost as valuable as living timber.

EXAMPLES.

CONIFERS.

Sawyers.—One of the striking examples of the destruction or deterioration of dying and dead timber familiar to all lumbermen is the injury to fire-killed and storm-felled white pine caused by boring grubs known as sawyers. Pine, fir, spruce, etc., are affected. These borers hatch from eggs deposited by the adult beetles in the bark of the dying trees, and after feeding on the inner bark for a time they enter the solid wood and extend their large burrows deep into the heartwood. Fire-killed white pine is especially liable to this injury, and is often so seriously damaged within three or four months during the warm season as to reduce materially the value of the attacked timber. The shortleaf, loblolly, and longleaf pine of the Southern States are damaged to a somewhat less extent, but examples are known of storm-felled timber within limited areas being reduced in value 25 to 35 per cent within three months after the storm. The fire and insect killed sugar pine, silver pine, and yellow pine of the western forests are also damaged in a similar manner, and the value of the product greatly reduced within a few months after the trees die. The losses from this secondary source in the coniferous forests contribute greatly to the annual waste of millions of dollars' worth of forest products.

Ambrosia beetles.—There is another class of wood-boring insects known as "timber beetles" or "ambrosia beetles," which cause pinhole defects principally in the sapwood, but some of them extend their burrows into the heartwood. These insects make their attack in the early stage of the declining or dying tree or before the sapwood has materially changed from the normal healthy condition, and often in such numbers as to perforate every square inch of wood.

The wood is thus not only rendered defective from the presence of pinholes, but the holes give entrance to a wood-staining fungus, which causes a rapid discoloration and still further deterioration of the product.

The value of the sapwood of trees dying from insect attack, fire, storm, and other causes is often reduced 50 per cent or more, and in some cases the value of the heartwood is reduced in a like manner 5 to 10 per cent.

Pin hole borers in cypress.—Another example of the destructive work of this class of insects is found in the cypress timber in the Gulf States, where the trees are deadened by the lumbermen and left standing several months or until it is dead and sufficiently dry to float. Upon investigation it was found that trees deadened at certain seasons of the year were attacked by the ambrosia beetles, and that in some cases the value of millions of feet of timber had thus been reduced 10 to 25 per cent or more.

HARDWOODS.

Roundheaded timber worms and ambrosia beetles.—The principal damage to dying and dead hardwood trees is caused by certain roundheaded (Cerambycid) wood borers, with habits similar to the sawyer, and by the timber worms mentioned as damaging living timber; also by ambrosia beetles, with habits similar to those that attack the sapwood and heartwood of conifers. All of the hardwoods suffer more or less, but the greatest damage is done to the wood of hickory, ash, oak, and chestnut, which are often reduced in value 10 to 25 per cent or more within the period in which the wood would otherwise be sound and available for utilization.

INJURY TO FOREST PRODUCTS.

During the process of utilizing forest resources, from the time the trees are felled until the logs are converted into the crude and finished product, and until the latter reaches the consumer, or even after it is placed in the finished article or structure, damage is caused by various species of insects which are attracted by the varying conditions prevailing at different stages in the process. As a result, additional drains are made on the timber to meet the demand for the higher grades of lumber and other supplies to replace that which has been injured or destroyed. From the writer's personal investigations of this subject in different sections of the country, the damage to forest products of various kinds from this cause seems to be far more extensive than is generally recognized. This loss differs from that resulting from insect damage to natural forest resources in that it represents more directly a loss of money invested in material and labor.

EXAMPLES.

Crude Products.

Roundheaded borers, timber worms, and ambrosia beetles.—Round timber with the bark on, such as saw logs, poles, posts, mine props, etc., are subject to serious damage by the same class of insects as those mentioned under character of injury to dying and dead trees.

The damage is especially severe when material is handled in such a manner as to offer favorable conditions for attack, such as leaving the logs in the woods on skidways or in mill yards for a month or more after they have been cut, when under such conditions there is often a reduction in value of from 5 to 30 per cent or more, due to wormhole and pinhole defects caused by roundheaded and flatheaded wood borers and timber beetles. Frequently the insects continue the work in the unseasoned and even dry lumber cut from logs which had been previously infested. They also continue to work in mine props after they have been placed in the mine, and in logs and other material used for the construction of cabins, rustic houses, etc., and in round timbers generally.

The products from saplings, such as hickory hoop poles and like material, are often seriously injured or rendered worthless by roundheaded and flat-headed borers and wood-boring beetles, sometimes resulting in a great loss of the merchantable product.

Stave and shingle bolts left in moist, shady places in the woods or in close piles during the summer months are often attacked by ambrosia beetles and timber beetles. The value of the product is, in consequence, often reduced 10 to 50 per cent or more.

Handle and wagon stock in the rough is especially liable to injury by ambrosia beetles and roundheaded borers. Hickory and ash with the bark on are almost certain to be greatly damaged if the logs and bolts cut from living trees during the winter and spring are held over a few weeks after the middle of March or first of April.

Pulp wood, and cord wood for fuel and other purposes, cut during the winter and spring and left in the woods for a few weeks or months, or in close piles after the beginning of the warm weather, are sometimes riddled with wormholes or converted into sawdust borings, causing a loss of from 10 to 100 per cent. One example reported from near Munising, Mich., represents a loss of $5,000 from injury to spruce and fir pulp wood cut in the winter and kept in piles over summer.

MANUFACTURED UNSEASONED PRODUCTS.

Ambrosia beetles and other wood borers.—Freshly sawed hardwood placed in close piles during warm, damp weather during the period from June to September is often seriously injured by ambrosia beetles. Heavy two to three inch stuff is also liable to attack by the same insects, even in loose piles. An example of this was found in some thousands of feet of mahogany lumber of the highest grade which had been sawed from imported round logs and piled with lumber sticks between each tier of plank where native species of ambrosia beetles, principally *Pterocyclon mali* Fitch, had entered the wood to such an extent as to have reduced the value 50 per cent or more within a few weeks. Oak, poplar, gum, and other similar woods often suffer severely from this class of injury, causing losses varying from 5 to 50 per cent.

Lumber and square timbers of both soft and hard woods with the bark left on the edges are frequently damaged by flat-headed and roundheaded wood borers which hatch from eggs deposited in the bark before or after the lumber is sawed. There are examples of losses from this character of injury amounting to 20 to 50 per cent or more.

Telegraph and telephone poles, posts, mine props, etc., are frequently injured before they are set in the ground, especially if the bark remains on them during a few weeks after the middle of March.

SEASONED PRODUCTS IN YARDS AND STOREHOUSES.

Powder post beetles.—Hardwood lumber of all kinds, rough handle and wagon stock, etc., partially or entirely of sapwood, are often reduced in value 10 to 90 per cent by a class of insects known as "powder post beetles." The sapwood of hickory, ash, and oak is most liable to attack. The reported losses from this source during the past five or six years indicate that there has been an average reduction in values of from 5 to 10 per cent or more.

Old hemlock and oak tan bark are often badly damaged by various insects which infest dead and dry bark that in some tanyards as much as 50 to 75 per cent of the bark that is over three years old is destroyed. In one tannery in West Virginia it is estimated that more than $30,000 worth of hemlock bark was thus destroyed.

FINISHED AND UTILIZED PRODUCTS.

FINISHED PRODUCTS.

Powder post beetles.—It is in the finished hardwood products, such as handles, wagon, carriage, and machinery stock, that the greatest damage and loss is occasioned by powder post beetles. This is especially true of hickory and ash handles and like products in storehouses, including the vast amount of material held in storage for the army and navy. When material of this kind is once attacked it is usually worthless for the purposes indicated, and therefore must be replaced with new material. In some cases losses have amounted to from 10 to 50 per cent, and it is estimated that the average losses have been as much as 10 per cent on all sapwood material that has been in storage more than one year.

UTILIZED PRODUCTS.

Powder post beetles and other wood borers.—The finished woodwork in implements, machinery, wagons, furniture, and inside finish in private and public buildings is often seriously damaged by powder post beetles.

Construction timbers and other woodwork in new and old buildings are often so seriously damaged by powder post beetles, white ants, and other wood-boring insects that the affected material has to be removed and replaced by new or the entire structure torn down and rebuilt.

Construction timbers in bridges and like structures, railroad ties, telephone and telegraph poles, mine props, fence posts, etc., are sometimes seriously injured by wood-boring grubs, termites, black ants, carpenter bees, and powder post beetles, and sometimes reduced in efficiency from 10 to 100 per cent.

INSECTS IN THEIR RELATION TO THE REDUCTION OF FUTURE SUPPLIES.

Insects not only reduce future supplies by killing the matured trees and destroying timber that is inaccessible for utilization, but through injuries during the flowering, fruiting, germinating, seedling, and sapling periods of early growth, prevent normal reproduction and development.

INTERRELATION OF INSECTS AND FIRE.

DURABILITY OF INSECT-KILLED TIMBER.

Timber killed by insects and fire would be available for utilization for many years were it not for injuries through secondary attacks of wood-boring insects and the destruction of insect-killed timber by forest fires. Some of the matured larch trees, evidently killed by the larch worm between 1881 and 1885, that had escaped subsequent depredations by fire and wood-boring insects, are now (1908) standing, and sound enough to be utiilzed for railroad ties and many other purposes. The heartwood of red spruce and Engelmann spruce, Douglas fir, white pine, etc., has been found by the writer to be sound enough for profitable utilization for pulp wood, lumber, fuel, etc., twenty to thirty years after it had been killed by insects or fire.

INSECT-KILLED TIMBER DESTROYED BY FIRE.

It has often happened that after insects had killed the timber over extensive areas forest fires followed and destroyed the dead timber. Indeed, abundant evidence has been found during recent investigations to prove that some of the denuded areas in the Rocky Mountain and other sections of the country are primarily due to devastations by insects, and that subsequent fires destroyed the timber and prevented reproduction.

FIRE-KILLED TIMBER INJURED BY INSECTS.

On the other hand, there is a vast amount of timber which has been killed outright or has died as the direct result of forest fires, but in every observed case insects have contributed more or less to the death of fire-scorched trees, which otherwise might have recovered, and especially to the rapid deterioration of a large per cent of the injured and killed trees. It is evident that in some cases fire-scorched and fire-killed timber has contributed to the multiplication of one or more of the destructive enemies to the living timber, and thus the injury started by the fire may have resulted in a destructive invasion of beetles. However, it is evident that this has happened only when the destructive beetle was already present in abnormal numbers in the forest surrounding the fire-swept area. Therefore, it is believed that injuries by fire are not as a rule an important factor in contributing to subsequent depredations by bark beetles. Such fires do, however, contribute to the multiplication of the insects which depredate on the wood, so that in forested areas where fires are frequent the damage to dying and dead trees is more severe, and fewer injured trees recover on account of the abundance of secondary bark-beetle enemies which do not, as a rule, attack living timber.

DESTRUCTION OF INSECTS BY FIRE.

There is another important feature in the relation of insects and fire, in which the fire contributes to the destruction of the principal bark-beetle enemies of the living timber. This happens when the fire burns the timber while it is infested, and thus effectually destroys the broods of the insects before they emerge. It is perfectly plain that the dying and dead foliage of the beetle-infested trees and the dead bark on the trunks would contribute to the starting and spread of crown fires, and thus the bark on the entire infested trunks would be sufficiently scorched to kill the insects. Therefore complete fire control may easily contribute to more extended depredations by insects on the living timber.

INTERRELATION OF FOREST INSECTS AND FOREST FUNGI.

DECAY FOLLOWS INJURY BY INSECTS.

It is well known that the burrows in the bark and wood of living and dead trees and in the crude and finished products often contribute to the entrance of bark and wood decaying fungi. Deterioration and decay are thus far more rapid than would otherwise be possible. It is also known that trees injured and dying from evident primary attack of parasitic fungi are attractive to certain insects which breed in the bark and wood of sickly and dying trees, and that certain other complicated troubles affecting forest trees are the result of an intimate interrelation and interdependence of insects and fungi. There can be no doubt, however, that certain species and classes of both insects and fungi are independently capable of attacking and killing perfectly vigorous and healthy trees.

BARK BEETLES KILL TREES IN AMERICA.

While there has been some question in European and other literature as to whether bark beetles ever attack healthy timber and kill it, the extended investigations by experts in this country, including detailed studies and experiments, have resulted in the accumulation of abundant evidence to prove conclusively that there are many species of bark beetles and other insects which not only attack perfectly healthy trees, but that they do so through preference and necessity. Furthermore, that they are not only capable of causing serious injury to trees during growth but they have killed century-old trees, and therefore are capable of killing a very large per cent of all of the pines, spruces, or larch within the area of their normal distribution.

SUMMARY OF CHARACTER AND EXTENT OF WASTE CAUSED BY INSECTS.

The killing of trees by insects; the damage to living timber and to crude and finished products by insects; the damage by fire following attack by insects after fire; and the damage from decay as the result of insect injury to trees previously injured and killed by both insects and fire, have been, and are now, continuing throughout the forested areas of the country, including private parks and the farmers' woodlots. Though not always evident in some forests or sections, yet every year, or series of years, there are conspicuous and widespread depredations somewhere in the forests of the country. In every forest and woodlot there is an ever-present but inconspicuous army of insects which requires for food and breeding places the bark, wood, foliage, and seeds of the various commercial tree species. The damage wrought in a single locality by these general enemies of the forests may not be noticed in a single year, but the accumulated injuries wrought during the period required for the growth of a tree from a seedling to commercial size goes far toward reducing the annual average increment below the point of profitable interest on private and public holdings.

The accumulated damage to crude, finished, and utilized products reduces the profits of the manufacturer, increases the price of the higher grades to the consumer, and results in an increased drain on the natural resources.

ESTIMATES.

In any attempt to estimate the extent of losses or waste of timber supplies to be expressed in dollars or feet, there are many conflicting factors which prevent reliable conclusions, in addition to the fact that we have no accurate information as to the actual amount in board feet of standing timber in the country and consequently no accurate data or average cash values. The same holds good, but to a less degree perhaps, with regard to percentages of damaged and destroyed supplies to that unaffected by insects. Therefore, until more complete data can be furnished by experts on forest statistics, any predictions must be based on estimated statistics and the facts and evidences observed by the writer and his field assistants, correspondents, etc., relating to the principal forest areas of the entire country, which are believed by the writer to be conservative, and he is confident that accurate statistics of the existing conditions in the country at this time would fully support it.

REDUCTIONS IN THE NATION'S WEALTH.

If the resources in merchantable timber and forest covers are considered as an element of the nation's wealth, as an asset of a given value to the people for direct utilization, protection to the land from erosion, protection of headwater streams and of game, and as contributing to the attractiveness of health and pleasure resorts, it would be difficult indeed to estimate the amount or per cent of losses or the reduction in values chargeable to insects. It is plain, however, that in the aggregate it would amount to an enormous sum.

REDUCTION IN VALUE OF COMMERCIAL AND FINISHED PRODUCTS.

If we consider the aggregate loss to the trade and to manufacturers and consumers of finished products caused by insects, it is evident that it would amount to many millions of dollars annually, in addition to increased drain on the forest to replace woods prematurely destroyed by insects.

METHODS OF PREVENTION AND CONTROL.

POSSIBILITIES OF CONTROL.

The results of extensive investigations and of practical applications during recent years have demonstrated that some of the most destructive insect enemies of American forests and of the manufactured and utilized products can be controlled, and serious damage prevented, with little or no ultimate cost over that involved in forest management and business methods.

There are, of course, certain insects and certain injuries which under present conditions and available information can not be controlled or prevented, but it is very evident that if the information now available through the publications of the Department of Agriculture and through direct correspondence with its experts be properly utilized in the future, it will result in the prevention of at least 30 per cent of the estimated annual waste of forest resources caused by insects.

GENERAL METHODS OF CONTROL.

The ordinary spraying and similar methods of dealing with fruit and shade tree insects are, of course, not available for practical application in the case of forest trees.

In all efforts to control an outbreak or prevent excessive losses, it should be remembered that as a rule it is useless to attempt the complete extermination of a given insect enemy of a forest tree or forest product. Experience has demonstrated that it is only necessary to reduce and weaken its forces at least 75 per cent, so that it can not continue an aggressive attack, but must occupy a defensive position against its own enemies and become dependent upon favorable conditions resulting from avoidable negligence and mismanagement by the owners of the forests and manufacturers of forest products, thus can be easily kept under control by good management.

The desired control or prevention of losses can often be brought about by the adoption or adjustment of the requisite details in forest management and in lumbering and manufacturing operations, storing, transporting, and utilizing the products, which at the least expenditure will cause the necessary reduction of the injurious insects and establish unfavorable conditions for their future multiplication or continuance of destructive work.

It is, however, of the utmost importance that any adjustment or modification in management or business methods should be based on expert technical knowledge or advice relating to the species, habits, life history, and natural enemies of the insects involved and on knowledge of the essential features of methods of control. This should be supplemented by expert knowledge or advice on the principles of technical and applied forestry in the proper management, care and utilization of the forests and its resources, and still further supplemented by practical knowledge and experience relating to local conditions and facilities.

As has been shown, the matured or merchantable-sized timber is most liable to injury or death from the ravages of insects. Therefore, considered from the standpoint of insect control and the prevention of one of the greatest items of loss, it is important that such timber should be utilized before it begins to deteriorate, or before it reaches the stage of unprofitable growth.

In order to be most successful in dealing with forest insects it must be recognized that each species differs to a greater or less extent from all other species, even of the same genus; that there are also certain characteristics of the different tree species which differ from those of all other tree species; and that as a rule it is the technical knowledge of these peculiar features or characteristics of the trees and their enemies which furnishes the clue to successful methods of control.

There are also many peculiar features in prevailing conditions in different localities, some of them favorable, others unfavorable, for the practical application according to a given method, so that while certain general advice may apply in a broad sense, it is often necessary to diagnose a given case before specific expert advice can be given as to the exact cause and the most effective method to be adopted, just as a physician must diagnose a case of illness or injury before prescribing the necessary treatment for his patient.

Therefore, in answering the question of the commission as to how far the waste of forest resources caused by insects can be prevented and how far the damaged timber can be utilized, we will attempt to give only general statements, based on the results of our observations, relating to some of the principal character of losses discussed in the first part of this report, namely, insects which (1) kill the trees, (2) cause injuries to the wood of living timber, (3) reduce future supplies, (4) cause injuries to the products; (5) the utilization of natural enemies of injurious insects, (6) the utilization of damaged timber, and (7) present conditions and opportunities.

CONTROL OF BARK BEETLES WHICH KILL TREES.

The bark beetles which kill trees attack the bark on the main trunk and destroy the life of the tree by extending their burrows or galleries in all directions through the inner living bark. The broods of young grubs or larvæ develop within the inner bark, on which they feed. Those of some species develop to the adult stage within the inner bark and are exposed when the bark is removed, while those of other species transform to the adults in the outer corky bark and the larvæ are not exposed when the bark is removed. Some species have two or more seasonal or annual generations, while others have but one, and in a few species it requires two years for a single generation to develop.

The bark beetles of the genus *Dendroctonus* represent the most destructive enemies of the principal coniferous American forests, and at the same time are among the easiest to control. The general requisites for success are embodied in the following rules:

(*a*) Give prompt attention to the first evidence of a destructive outbreak, as indicated by an abnormal per cent of yellow or red topped dying trees, and especially when such trees occur in groups of 10 or more or cover large areas; (*b*) secure authentic determination of the particular species of insect responsible for the trouble; and (*c*) take prompt action toward their control according to specific expert advice on the best method for the destruction of the necessary 75 per cent or more of the insects in the infested trees.

Some of the methods to be adopted to meet the requirements of various local conditions are as follows:

1. Utilize the infested timber and burn the slabs during the period in which the broods of the destructive beetles are in the immature stages or before the developed broods emerge from the bark; or
2. Fell the infested trees and remove the bark from the main trunk and burn the bark, if necessary;[a] or
3. Remove the infested bark from the standing timber and burn the bark, when necessary;[a] or
4. Immerse the unbarked logs in ponds, lakes, or streams, where the bark will remain soaked long enough to kill the insects; or
5. Remove the unbarked logs or products to a locality where there are no trees liable to attack within a radius of 20 miles or more.

TO MAINTAIN CONTROL OF BARK BEETLES.

Future trouble of a serious nature from this class of insects can be prevented if an insect-control policy is adopted in connection with, or independent of, a fire-control policy by which groups of dying trees will receive the same prompt attention as that given to forest fires.

Applications in state and national forests.—In all forest reserves in which there is an organized force of rangers and firewardens or opatrols, each officer should be furnished with instructions as to the location of beetle-infested trees, and with equipments and directions for taking the necessary action whenever the conditions demand it.

Private forests.—Private forests should receive the same attention as public forests, but it is often far more difficult on account of intervening forests, where the owners either can not or will not give the matter the required attention. While it may be advisable to have some laws to govern the treatment of timber infested with a dangerous pest when the owner refuses to take any action, such laws should apply only to the more extreme cases or as a last resort on authoritative advice. It is probable that in most cases legislation will not be necessary, and more ultimate good will result without than with strict laws, especially when it can be made clear to the owner that his personal interests demand that he take the proper action and that, when necessary, his neighbors will render assistance, as is often done in the case of a forest fire.

Inaccessible areas.—There are yet large, inaccessible areas in the East and West where it is not practicable or possible at present to attempt to control the depredations by these beetles, and therefore they must be left to the natural adjustment that has been going on in all primitive forests from the beginning. While under such natural control much of the older matured timber will be lost, it will usually be replaced by young growth, either of the same or of different species, so that under normal conditions the forest will be perpetuated, but under exceptional conditions and combinations of detrimental influences, such as secondary insect enemies, fire, drought, etc., extensive areas may be completely denuded, never to be reforested under natural conditions. Therefore it will evidently not be very long before it will pay to adopt insect-control policies in areas that are inaccessible for profitable lumbering.

---

[a] If the broods develop to adults in the outer bark it must be burned; if they develop in the inner bark and are exposed when the bark is removed, burning is not necessary. As a rule the burning of the tops to destroy the insects is not necessary.

EXAMPLES OF SUCCESSFUL CONTROL OF BARK BEETLES.

The following examples of successful control of depredations by the destructive bark beetles are sufficient to demonstrate the practicability of advice based on the results of entomological investigations.

CONTROL OF THE EASTERN SPRUCE BEETLE.

The control of an alarming outbreak of the eastern spruce beetle (*Dendroctonus piceaperda* Hopk.) in northeastern Maine in 1900 and 1901 was effected by the concentration of regular logging operations in the areas of infested timber and placing the logs in lakes and streams and driving them to the mills on the Androscoggin River. Thus, with little or no additional expense, there was a saving to one firm, according to its estimates, of more than $100,000.

CONTROL OF THE BLACK HILLS BEETLE.

An extensive outbreak of the Black Hills beetle (*Dendroctonus ponderosæ* Hopk.) in the vicinity of Colorado Springs, Colo., in 1905–6, which was threatening the living pine timber of the entire section, was brought under control through the efforts of the private owners of forests and of officials in the adjoining national forests, by cutting and barking about 1,000 beetle-infested and beetle-killed pine trees. The cost of the operations was largely, if not entirely, covered by the utilized felled timber, although considerable unnecessary expense was involved through the felling and barking of trees from which the beetles had emerged, also from the unnecessary burning of the bark and tops.

The successful control of another serious outbreak of the Black Hills beetle in 1906 on an extensive private estate in southern Colorado was effected through the efforts of the owners, who had some 500 infested trees felled and barked within the necessary period to destroy the broods. A large per cent but not all of the infested timber was thus treated. So thorough was the work that not a single infested and dying tree could be found when the area was inspected in 1908. In this, as in the other case, considerable unnecessary expense was involved in the burning of the bark and tops, but the utilizable timber was worth more than enough to pay all expenses. It is evident that in this case a destructive invasion was prevented.

The most striking example of success in control of the Black Hills beetle has recently been reported. In May, 1907, Mr. W. D. Edmonston, a forest ranger, detailed from the Forest Service to the Bureau of Entomology, to work under our instructions in locations of beetle infestation in the national forests of Colorado and adjoining States, reported that the pine timber was dying on a large estate not far from Idaho Springs, Colo., and in the adjoining Pike National Forest. Mr. Edmonston was then instructed to make more detailed examinations, after which he reported that some 63,000 feet of standing timber on the estate was infested by the Black Hills beetle, and that unless the ravages were checked at once it would kill the timber not only on this estate but that on the adjoining estates and national forest. The owner of the property was advised by the Bureau of Entomology to take radical action, but no action was taken before the first of the following July, and therefore not in time to prevent the broods of beetles from swarming from the infested trees and extending their ravages.

In December, 1907, Mr. Edmonston was instructed to make another examination of the timber, when he found that his prediction was being fulfilled, and that instead of 65,000 feet of timber in the old infestation there was nearly four times as much timber involved in the new, or over 250,000 feet. The owner was again notified of the serious character of the outbreak, and further suggestion made that if the logs from the infested trees were converted into lumber and the slabs burned before May, 1908, it would result in the protection of the remaining living timber. Immediate steps were then taken by the owners to carry out the original recommendations. Mr. Edmonston gave instructions to the manager of the estate in locating and marking the infested trees and in the best methods of destroying the beetles; he also marked infested timber on an adjoining estate and on the national forest. Five months later, in May, 1908, Mr. Edmonston reported that the larger clumps of infested trees on the estate had been converted into lumber and the slabs burned, and that the marked trees on the adjoining estate and national forest had been cut and barked. In November, 1908, Mr. Edmonston was instructed to make another inspection of the forest on the estate and surrounding area, and on December 1 he reported:

> Nothing could be more satisfactory than the results obtained by the cutting of the infested timber on the estate. Your recommendations and instructions submitted to the owner, and carefully followed by the manager of the estate, have clearly demonstrated that insect infestation can be controlled and at no expense to the owner of the timber involved; in fact, a very satisfactory price was realized, resulting in a net profit, I understand, of $5 per thousand feet b. m. on the 240,000 feet cut. This, of course, does not include the profit of the milling operations, but for the logs sold at the mill, after deducting the expenses of cutting and logging. The sawmill was owned and operated by an Idaho Springs firm, and the manufactured article sold in that town. I spent six days on the estate, November 18 to 23. After a very thorough examination of the timber, I found only three infested trees, isolated individuals, and over a mile from where the large clumps of infested trees were cut. With the exception of those three trees, there is no new infestation on the estate. I also examined the adjoining lands, but no new infestation was observed. The infested trees which I marked in December, 1907, had been cut and barked. On the Pike National Forest, contiguous to the first-mentioned estate, where you will remember I marked some clumps of infested trees, no new infestation was found—not one tree. I found that all the infested trees I marked had been cut and barked. Ranger Kelso had charge of this work, and it has been quite thoroughly done.

This most gratifying result demonstrated two important things; one, that a quite extensive outbreak by one of the *Dendroctonus* beetles, involving near 1,000 trees, can be controlled without expense, and even at a profit, whenever the conditions are favorable for the utilization of the infested timber; the other that the essential details of the recommendations and expert advice based on the results of scientific research can be successfully applied by a manager of a private forest or by the rangers of national and state forests. It also indicates quite conclusively that the widespread depredations in the

Black Hills Forest Reserve could have been prevented with very little expense to the Government if the matter had received prompt attention in 1901, when the first investigations were made and essentially the same recommendations submitted. But, through the lack of public appreciation of the importance of the problem at the time, and the lack of sufficient authority and funds later, infestation was allowed to extend beyond practical control, and in consequence a large per cent of the timber of the entire national forest has been killed. There were then no forcible examples of the practical value of such recommendations based on scientific research, and no other argument was effective in arousing public interest in the threatening character of the outbreak. Now we have several examples demonstrating the practicability of forest-insect control in America which should lead to confidence in the results of research as a basis for successful practical application.

CONTROL OF HICKORY BARK BEETLE.

The complete control of the hickory bark beetle, whose ravages threatened the total destruction of the hickory trees on Belle Isle Park, at Detroit, Mich., in 1903, was effected by felling and removing the infested trees and converting them into merchantable products, all without cost to the park commission.

CONTROL OF INSECTS WHICH CAUSE DEFECTS IN LIVING TIMBER.

The class of insects which cause defects in the wood of living timber can be controlled to a greater or less extent, depending upon local conditions, and a large per cent of the losses can be prevented through the adoption of certain requisite details in forest management, especially (*a*) the utilization of all of the defective and infested timber that will pay expenses for manufacture into merchantable products, such as lumber, cordwood, etc.; (*b*) the burning of infested timber and waste material not available for use, including dead standing and down timber, to remove the breeding places of insects such as the oak timber worm and the chestnut timber worm, which insects go from the dead timber to the living; (*c*) the prevention of wounds of any kind in the bark of living trees; and finally (*d*) to prevent future losses by the practice of improved forestry methods, which will eliminate favorable conditions for injury and contribute to a perpetual supply of vigorous, healthy timber to be utilized before it passes the stage of profitable increment.

PREVENTION OF INJURY TO DYING AND DEAD TREES.

A large per cent of the injury to insect, fire, and lightning killed trees and trees killed or dying from injuries by storms, disease, etc., can be prevented—

1. By the prompt utilization of such timber within a few weeks or months after it is dead or found to be past recovery;
2. By removing the bark from the merchantable portions of the trunks within a few weeks after the trees are dead;
3. By felling the trees and placing the unbarked logs in water;
4. And, finally, by the adoption of a system of forest management which will provide for the prompt utilization of all trees which die from any cause.

PREVENTION OF LOSSES FROM INSECT INJURIES TO NATURAL AND ARTIFICIAL REPRODUCTION.

The successful control of insects which destroy or prevent the normal development of natural reproduction is a far more difficult problem than that presented by other classes of insect injuries, but in this, as in the others, a great deal can be accomplished toward preventing the reduction of future supplies.

Much can be accomplished in the nursery and on small plantations by the adoption of the ordinary methods of controlling farm and orchard insects, but in the natural forests reliance must be placed largely on systems of forest management.

UTILIZATION OF IMMUNE AND RESISTANT VARIETIES AND RACES OF TREES.

Certain individuals representing varietal or racial forms of trees of a given species are sometimes found to be either immune or decidedly more resistant to the insects which are destructive or seriously injurious to the life or wood of other individuals or varieties of the same species. This fact suggests the importance of recognizing the well-known principle of improvement by selection. Thus selecting seed or cuttings from such immune and resistant trees for artificial propagation, or taking great pains to leave such trees in commercial or selection cuttings, will undoubtedly be an important step toward providing against damage and losses in the future.

PREVENTION OF INSECT INJURIES TO FOREST PRODUCTS.

CRUDE PRODUCTS.

The problem of artificial control and prevention of insect injuries to forest products offers less difficulties perhaps than that relating to many other branches of the general subject of forest insect control.

In most cases the principle of prevention is the only one to be considered, since the damage is done soon after the insects enter the wood and therefore it can not be repaired by destroying the enemy.

Crude Products.

The degree of moisture found in the bark and wood of newly felled trees, saw logs, telegraph poles, posts, and like material cut in the fall and winter and left on the ground or in close piles during a few weeks or months in the spring and summer, or during the period when the particular species of injurious insects are flying, is one of the conditions most favorable to attack. This period of danger varies with the kind of timber and the time of the year when felled. Those trees felled in late fall and winter will generally remain attractive to ambrosia beetles and the adults of round and flat headed borers during March, April, and May. Those felled during the period between April and September may be attacked in a few days after they are felled, but the period of danger may not extend over more than a few weeks. Thus certain kinds of trees felled during certain seasons may never be attacked, while if felled at other seasons the conditions for attack may be most favorable if insects are active, and then the wood will be thickly infested and ruined. The presence of bark is absolutely necessary for successful infestation by most of the wood-boring grubs, because the eggs and young must occupy the inner and outer portions before the latter can enter the wood. Some ambrosia beetles and timber worms will, however, attack barked logs, especially those in close piles or otherwise shaded or protected from rapid drying. A large per cent of the injury to this class of products can be prevented—

1. By providing for as little delay as possible between the felling of the tree and its manufacture into rough products. This is especially necessary with trees felled from April to September in the region north of the Gulf States and from March to November in the Gulf States, while the late fall and winter cuttings should all be worked up by March or April;

2. By removing the round timbers from the woods and skidways during the danger period, or if this is impossible, by taking every precaution to facilitate the rapid drying of the inner bark by keeping the logs off the ground, in the sun, or in loose piles; or else the opposite extreme should be adopted and the logs kept in water;

3. By the removal of the bark from poles, posts, and other material which will not be injured by checking or season cracks, within a few days after the trees are felled;

4. By working in the proper months or seasons to fell or girdle different kinds of trees.

Damage to products cut from saplings and left with the bark on can be prevented by transporting the material from the woods soon after it is cut, so it will not be left in piles or bundles in or near the forest during the season of insect activity, also by frequent change of place of storage.

Pin-hole damage to stave and shingle bolts cut during a warm season can be prevented by removing the bark from the timber as soon as it is felled and by converting the bolts into the smallest practicable dimensions and piling them in such a manner as to facilitate rapid drying.

Damage to unseasoned handle and wagon stock in the rough can be prevented by taking special precautions to provide against the same favorable conditions for attack as mentioned in connection with round timbers. This is especially necessary with hickory and ash if cut during the winter and spring.

Damage to pulp wood and cord wood can be prevented to a great extent by placing the sticks in triangular or crib piles immediately after they are cut from the trees, especially if the timber is cut during the danger period or must be held over a few months during the warm season. Peeling or splitting the wood, or both, before it is piled will also provide against damage from insects.

Manufactured Products.

UNSEASONED PRODUCTS.

Freshly sawed hard-wood lumber placed in close piles during warm damp weather, within the period from July to September, inclusive, presents the most favorable conditions for injury by ambrosia beetles. In all cases it is the moist condition and retarded drying of the lumber which induces attack. Therefore any method which will provide for the rapid drying of the lumber before or after piling will tend to prevent losses. It is important also that heavy lumber should, as far as possible, be cut only in the winter and piled so that it will be well dried out before the middle of March.

The damage to lumber and square timber when the bark is left on the edges or sides can be prevented by removing the bark before or immediately after the lumber is sawed, or by sawing and piling the material during the winter, or if sawn at other times, piling it so as to facilitate rapid drying.

SEASONED PRODUCTS.

Unfinished seasoned products.—Injury by powder-post beetles to dry hard-wood lumber and other material in stacks or storehouses can be prevented—

1. By a general inspection of the material in the yards and storehouses at least once a year, preferably during November or February, for the purpose of sorting out and disposing of any material that shows the slightest evidence of injury, as indicated by the presence of fine powdery boring dust;

2. By preventing the introduction into lumber yards or storehouses of any infested material, remembering that the insect may be thus distributed to all parts of the world;

3. By the adoption of a system of classification of all dry or seasoned hard-wood stock which will provide for (*a*) the separation of the pure heartwood material from the pure and part sapwood material; (*b*) classification of all kinds of wood most liable to attack, such as hickory, ash, oak; (*c*) the successive utilization or sale of the older material (remembering that material one year old or over is far more liable to injury); and (*d*) providing against the accumulation of refuse material in which the insects could breed.

Finished products.—Damage to finished handles, oars, spokes, rims, hubs, wheels, and other unpainted wagon, carriage, machinery, and implement stock in factories, wholesale and retail storehouses, army and navy stores, can be prevented by the adoption of the same general rules as those given under rough products. In addition, damage can be controlled and prevented—(*a*) by sorting out and destroying all articles showing the slightest evidence of powder-post injury, or (*b*) treating with kerosene oil such infested and slightly injured articles as may be tested for required strength and found to be of sufficient value to retain, the same to be placed in quarantine a sufficient length of time to determine whether the treatment is successful.

Damage by insects to many articles can be prevented, and at the same time the material benefited, by treating the wood with linseed oil, either by immersion in the oil or by application with a brush, the application to be made as soon as possible after the articles are finished.

PAST AND PRESENT CONDITIONS OF POWDER-POST INJURY.

Up to 1906 there were a great many reports of extensive losses of valuable material from the extensive ravages of powder-post beetles, which were seriously affecting all industries involved in the manufacture, sale, and utilization of the classes of hard-wood products. In response to these reports and accompanying appeals to the Department of Agriculture for information on causes and remedies, the problem was thoroughly investigated, and specific advice and instructions relating to practical methods of control and prevention have been widely disseminated, both through publications of the department and special correspondence.

Reports of present conditions, with fewer requests for advice, indicate that the disseminated information has been extensively utilized and that it has been worth many millions of dollars toward eliminating the losses and reducing the drain on the limited supply of the kinds of timber required to replenish the damaged and destroyed material.

The army and navy stores of handles, tent poles, wheelbarrows, oars, and many other hard-wood articles have suffered severely from powder-post damage, but the information supplied has contributed greatly toward the elimination of this source of loss to the Government.

TAN BARK.

Damage to hemlock and oak tan bark by the class of insects which in some cases have been so destructive to this class of products in the past can be easily prevented without cost—

1. By utilizing the bark within three years from the time it is taken from the trees;
2. By preventing the accumulation in the yards and store sheds of old waste material in which the insects can breed.

These simple methods have been extensively adopted since their recommendation in correspondence and publications between about 1894 and 1904, and constitute one of the most striking examples of the value of expert information on the peculiar habits of insects and of how millions of dollars can be saved by exercising a little judgment.

UTILIZED PRODUCTS.

Damage and losses from insect injuries to timber and other woodwork in structures of various kinds, to telephone and telegraph poles, posts, railroad ties, mine props, etc., can be prevented by treating the material with preservatives.

TIMBERS AND WOODWORK IN STRUCTURES.

Injuries to timbers and woodwork in dwellings, outbuildings, bridges, etc., by powder-post insects can be prevented—

1. By the use of heartwood only for the concealed parts most liable to be damaged;
2. If it is necessary to use all or part sapwood material, attack can be prevented by treating the sap portions with kerosene, coal tar, creosote, or linseed oil. Facilities for future treatment can be provided wherever the rough or finished woodwork is exposed, as in outbuildings, bridges, etc., if care is taken to expose the sapwood portions;

3. If the timbers and woodwork in old buildings show evidence of attack, the affected portions should be treated with a liberal application of kerosene.

Damage by white ants or termites can often be prevented—

1. By the use of sound wood only for underpinning and foundation timbers and the removal of decaying timbers from old structures;
2. By preventing abnormal moist conditions of the wood in any part of the structure, and especially of that in foundation timbers;
3. By the treatment with creosote, zinc chloride, corrosive sublimate, etc., of timbers necessarily exposed to moist conditions;
4. If the timbers become infested, further injury can be prevented by removing the badly damaged parts and soaking the remainder with kerosene, fumigating with bisulphide of carbon, and by removing any adjacent wood in which the insects may breed, such as logs, stumps, etc.

LOG CABINS AND RUSTIC WORK.

Damage by bark and wood boring insects to the unbarked logs and poles used in rustic cabins, summer houses, fences, etc., can be largely prevented by cutting the material in October and November and utilizing it at once, or by piling it off the ground or under cover in such a manner as to offer the best facilities for the rapid and thorough drying of the inner bark before the middle of March or the first of April following. If this precaution is not taken and there is evidence that insects are at work, the damage can be checked by injecting bisulphide of carbon through natural or artificial openings in the affected bark and immediately stopping these and other openings with putty or a similar substance.

POLES, POSTS, TIES, MINE PROPS, AND SIMILAR PRODUCTS.

Insect damage to poles, posts, and similar products can be prevented to a greater or less extent by the preservative treatments which have been tested and recommended by the Forest Service. These should be applied before the material is utilized, or if attacked after it has been utilized, further damage can be checked to a certain extent in like manner.

It is of prime importance to prevent injury from wood-boring insects because such injuries contribute to more rapid decay.

UTILIZATION OF NATURAL ENEMIES OF INJURIOUS INSECTS.

Were it not for the natural checks of control of some of the more destructive insect enemies of forest trees and products, successful artificial control would, in many cases, be impossible, and the depredations would be far more complete. These natural enemies of the depredating insects consist of parasitic and predatory insects, diseases of insects, birds, adverse climatic conditions, etc. While one or more of these beneficial factors exerts a continuous and powerful influence toward the prevention of a more extensive waste, it has been repeatedly demonstrated that these checks can not always be depended upon to prevent widespread devastations by protecting the best trees and the best tree species. The insects and birds which prey upon the depredating insects also have enemies consisting of insects, birds, diseases, and climatic conditions. Therefore under normal conditions the tendency is toward the preservation of a balance between the warring factors, but frequently the enemies of the trees get the ascendency and take the character of an invasion, which may continue for two or three or even ten years before the balance is restored. Thus a vast amount of timber or a given forest product may be destroyed before the factors of natural control can prevail.

It is evident that the most effective utilization of the factors of natural control will be through our assisting in the destruction of the enemy rather than through the artificial introduction of such factors. The former is accomplished by the adoption of methods of combating the invaders which will reduce their forces below the power of attack, or by reducing their numbers to the point where they must occupy a defensive position against their natural enemies and become dependent for their supplies of food and breeding places upon that avoidably furnished through mismanagement of the forests and manufacturing operations. Thus we can contribute greatly toward the preservation of a balance which will be to our material benefit. On the other hand, we may in the future, as we have in the past, contribute greatly to the multiplication of the depredating insects and to greatly increased losses caused by them through ignorance or disregard of the fundamental principle of insect control in the management of forest and manufacturing enterprises.

BENEFICIAL INSECTS.

The beneficial insects comprise those which are internal or external parasites of the immature or matured stages of the injurious insects, also those which feed on the young or adults. These two classes are doubtless far more effective in the long run than any other set of agencies of natural control. Yet they, in combination with all other factors, can not be always relied upon to render the desired service of continued and efficient control. They can, however, be relied upon to respond to artificial assistance in the reducing of the depredators or to proper artificial introduction and distribution.

BENEFICIAL DISEASES OF INSECTS.

It is very evident that the parasitic fungi and bacteria which sometimes cause epidemics among injurious insects often exert a powerful influence toward the control of extensive outbreaks or invasions of insect enemies of forests. Indeed, it appears that the greatest service rendered by this class of natural enemies is in the often sudden appearance of an epidemic which kills off a destructive species of insect, which has increased to such numbers and extended its depredations over such vast areas as to be far beyond the control of man or his insect and bird allies. Numerous examples of this kind of natural control are found in widespread depredations by various species of caterpillars and sawfly larvæ which defoliate deciduous and coniferous trees. As a rule, however, the beneficial effects of the diseases of insects prevail only after the injurious insects have increased to excessive numbers. Therefore this factor of insect control can not be depended upon to hold the insects in check or prevent outbreaks. The fact, however, that it operates on a class of insect enemies of the forest (defoliators) which can not be controlled by any known artificial methods renders the services of the diseases all the more valuable.

It is believed that with further knowledge of nature's method of propagating, perpetuating, and disseminating epidemics among insects, they can be utilized more or less successfully through artificial propagation and dissemination to head off threatened invasions by defoliating insects.

BENEFICIAL BIRDS.

That certain classes of birds, such as woodpeckers, render valuable service toward the natural control of certain destructive bark and wood boring insects is very evident. They appear to render the greatest service, however, where but few trees are being killed or injured, because their concentrated work on such trees may contribute toward the prevention of an abnormal increase of the insects. They also render some service as allies of the other beneficial factors which assist in artificial control. It is evident, however, that where many hundreds or thousands of trees are being killed, the comparatively limited number of birds in any forest under the most favorable conditions can have little beneficial effect. Therefore, while the birds should be classed among the valuable friends of the forest and should be protected, it is plain that they can not, even with the utmost protection, always be relied upon to protect the forest against destructive ravages of insects.

We must remember in this connection that there are complicated interrelations between birds, injurious insects, and beneficial insects which do not necessarily operate to the benefit of the forest. In fact, it may sometimes happen to be quite the reverse. Therefore, in order to derive the greatest benefit from the conflict between the birds, the insect enemies of the trees, and the insect friends of the trees, we must utilize our knowledge of the factors which are contributing toward the preservation of a balance, so that whenever the enemies of the forest threaten to get beyond natural control, we may enter the field and through artificial means endeavor to force them back to their normal defensive position.

BENEFICIAL CLIMATIC CONDITIONS.

The benefits to be derived from climatic conditions which are detrimental or destructive to insect enemies of the forest, while sometimes very great, are necessarily unreliable and thus can not be depended upon to assist in artificial control. In fact, the very condition which may contribute to the destruction of one depredator may favor the multiplication of another.

UTILIZATION OF WASTE CAUSED BY INSECTS.

When we come to consider the vast amount of standing timber in the forests of the country which has been injured or killed by insects, and which will go to waste if it is not utilized within a limited period, we realize the importance of removing the insect-infested timber, because in doing so we contribute more, perhaps, than in any other way to the reduction of the insects, and thus provide against serious injury in the future, as well as to the maintenance of control.

PRESENT CONDITIONS AND OPPORTUNITIES.

Unfortunately, the examples of management, or rather mismanagement, which are contributing to an increase of waste are far in excess of instances of proper management. This is due in a large part to the conditions that have prevailed in American forests in the past which have rendered it impracticable to adopt improved policies of forest management, but at present it is largely due to a lack of appreciation of the importance of the subject, and of the opportunities to prevent such losses, when it is not only practicable, but possible, to do so, and will at the same time yield large returns on the necessary additional expense. This is especially true in thousands of farmers' woodlots and private holdings in the States east of the Mississippi River, in which from 25 to 90 per cent of all of the serious injury of the past can be prevented in the future with little or no additional expense over that required for ordinary good forest management.

FOREST ENTOMOLOGY, AS APPLIED TO AMERICAN FORESTS.

It is only within the past eleven years that any attempt has been made toward a systematic investigation of the insect enemies of the forest trees and forest products of the entire country. The state of knowledge of the subject previous to that time can be judged by the fact that a number of the most destructive enemies of forest trees are found to be new to science and that nothing whatever was known of the habits and seasonal history of a large number of the more important known species which are common enemies of forest trees and forest products, and that scarcely anything was known in regard to practical methods of controlling the enemies or of preventing losses from their ravages.

PRESENT KNOWLEDGE.

Within the past ten years forest-insect investigations have been conducted by the Bureau of Entomology of the Department of Agriculture in all of the principal forest regions of the United States, which have led to the following results:

RESULTS OF INVESTIGATIONS.

Satisfactory progress has been made toward the attainment of some of the fundamental objects of the investigations, one of which has been the laying of a substantial foundation for forest entomology in this country, on which future progress can be made along the lines of acquiring, disseminating, and applying information of immediate practical value in the protection of our forest resources.

ACQUIRED OR NEW INFORMATION.

The principal insect enemies of the forest and forest products of North America and the general character and extent of their depredations have been determined.

The more important facts in the life history, habits, and practical methods of control relating to some of the more destructive insects have been determined.

A mass of original data has been collected relating to forest insects in general, including not only those which are destructive or injurious, but those which are beneficial or neutral in their relation to [illegible] forest, as represented by a collection of more than a million specimens of insects and their work.

As a direct result of the investigations of forest insects during the past six years, at a cost of less than $53,000, there has been accumulated a reserve fund of information now available through publications, correspondence, and field demonstrations, which, if properly utilized for practical application, would evidently prevent from 10 to 30 per cent of the annual losses at a very small cost.

DISSEMINATED INFORMATION.

In addition to information disseminated to all sections of the country through correspondence, lectures, demonstrations, exhibitions, etc., the published information, based on the results of investigations conducted by the West Virginia Experiment Station and the Bureau of Entomology of the U. S. Department of Agriculture during the past eighteen years is represented by over 1,300 pages, 99 plates, and 340 figures.

NEEDS.

The work that has been done is only a beginning in the vast field of forest entomology. There is need of more systematic work (or so-called pure science) on the different stages of the thousands of species of injurious and beneficial insects involved. This is absolutely necessary in order to have further scientific basis of facts on which to build the structure of complex details necessary to success in practical application in its broadest sense.

There is need of further detailed studies of habits and seasonal histories of the species of injurious and beneficial insects, as well as of the local and other conditions favorable and unfavorable for their multiplication and work.

Further information is desirable on the principal factors of natural control, in order that it may be better utilized to facilitate artificial control.

There is special need of more general information on, and public interest in, the subject of losses from insect depredations on standing timber and timber products, and a better realization of the possibility and practicability of preventing losses.

Looking to this end, there is need of further demonstration and educational work along the lines which will bring the matter to the attention of the man in the woods, sawmill, factory, or trade, who is in direct touch with the local conditions and business methods.

There is a special need of more experts in forest entomology, and there will be an increasing demand for such experts in the future to organize and take charge of insect-control policies in state forests, public parks, the more extensive private or commercial forests, and in extensive manufacturing enterprises, and also to give instructions to students in forestry schools and forestry departments in state and other institutions of learning.

The need of trained and experienced experts in forest entomology for all of this class of work can not be too strongly urged. There is, perhaps, no branch of economic or applied science which requires more technical knowledge and practical experience as a basis for proper investigations and authentic instructions and advice than forest entomology, and there is perhaps no other feature in the science and practice of forestry in which advice and application based on insufficient knowledge is so dangerous.

There is quite general recognition of the importance of guarding against contagious diseases, and of consulting a physician in a case of serious illness, and of the necessity of relying on an authorized pharmacist to fill a prescription, and of administering the prescribed treatment according to directions, but it is a notable fact that comparatively few persons, even when deeply interested in preserving the health of the forest, have heretofore recognized the importance of guarding against insect epidemics or of consulting an expert forest entomologist in the case of threatened or existing depredations. It has often happened that when such advice has been sought and received, the treatment was not administered according to the recommendations, but changed to suit the ideas of some one entirely ignorant of the facts and principles on which it was based. Thus not only the accomplishment of the desired results failed, but often contributed to an aggravation of the trouble and increased losses. The determination of the causes of specific troubles affecting the individuals of a given species of forest tree or an injury to a given type of product is just as complicated and requires the same elements of experience, training, and skill as that required for the determination of the cause of a given disease or the character of a given injury affecting man, and it is just as important to know the cause or character of injury in the former as it is in the latter, in order to prescribe the specific treatment which will yield the desired results.

Therefore, in order to make the best progress toward preventing future waste of our forest resources from depredations by insects, every one interested in the subject, and especially those in authority in public and private institutions of investigation and learning, should see to it that the character of instructions to students and of the information given out to the public is not only the best available, but that it is limited to the range of expert knowledge of the subject possessed by the instructor or investigator.

ELEMENTARY AND TECHNICAL KNOWLEDGE OF FOREST ENTOMOLOGY FOR THE FORESTER.

While it may be desirable that every professional forester should have an expert knowledge of forest entomology, it is rarely possible except under certain favorable conditions for him to acquire more than the necessary elementary knowledge, and even this has not been possible under the conditions which have necessarily prevailed in the forest schools and in the practice of forestry in this country, and little or no time has been available for acquiring the necessary information from subsequent study or experience. Therefore this feature in the education of the American forester has been practically neglected.

PRESENT REQUIREMENTS OF INSTRUCTION.

As long as expert forest entomologists and authentic text-books based on American insects and conditions are not available for giving a complete course in technical and applied forest entomology, the requirements of such a course should be limited to instruction in elementary entomology and elementary principles of applied forest entomology, which will give the necessary foundation for intelligent observations and utilization of available information as required in future practice.

SUMMARY.

There is conclusive evidence that insects have been in the past, and are now, important factors in the waste and reduction of timber supplies, and will continue to be in the future.

They attack perfectly healthy trees of all ages and kill them.

They have killed a large per cent of the best timber over thousands of square miles of heavily forested lands.

They reduce the value of living timber and that of crude, finished, and utilized products.

HOW LOSSES CAN BE PREVENTED.

The results of extensive investigations and of practical applications during recent years have demonstrated that some of the most destructive insect enemies of American forests, and of manufactured and utilized products, can be controlled and serious damage prevented with little or no ultimate cost over that involved in good forest management and business methods.

It is evident that if the information now available through publications of the Department of Agriculture and through direct correspondence with its experts is properly utilized in the future, it will result in the prevention of an equivalent of at least 30 per cent of the estimated annual waste of forest resources caused by insects, and thus contribute greatly to the conservation of forest resources.

This can be accomplished—

(1) By the adoption or adjustment of certain requisite details in forest management, lumbering and manufacturing operations, and in storing, transporting, and utilizing the products which adoption, at the least expense, will bring about the necessary reduction of injurious insects and prevent their future multiplication or destructive work.

(2) By the adoption of policies of control based upon expert technical knowledge or advice relating to the species, habits, life history, and natural enemies of the insects involved, supplemented by knowledge of the proper management, care, and utilization of the forest and its resources, and by practical knowledge and experience relating to local conditions and facilities.

(3) Reliance on technical advice furnished by recognized experts in forest entomology and forestry as a basis for success in practical application by the owner or forester.

(4) Utilization of so-called matured timber, and especially of dense or pure stands of such timber, thus removing one of the favorable conditions for rapid deterioration through attacks by wood-boring

insects or the death of the timber through the attack of destructive bark-boring or defoliating insects.

(5) As a rule, it is useless to attempt the extermination of an insect enemy of the forest or its products. It is only necessary to reduce and weaken its forces, so that it can not continue an aggressive invasion, but must occupy a defensive position against its own enemies and become dependent upon conditions resulting from avoidable negligence and mismanagement by the owners of the forests and the manufacturers of forest products.

(6) The utilization of a knowledge of the principles of natural control as a means of contributing to the efficiency of artificial control.

(7) Prompt recognition of the first evidences of a destructive outbreak of the principal insect depredators, authentic identification of the species involved, and prompt action in adopting the proper method or methods of control.

While beneficial insects, beneficial birds, and beneficial diseases exert a continuous and powerful influence toward the prevention of a more extensive waste of forest resources, it has been repeatedly demonstrated that they can not always be depended upon to prevent widespread devastations or to otherwise work for the best interests of the private or public owner by protecting the best trees and the best tree species.

The best way to utilize the factors of natural control is to become their allies and assist in the reduction of the enemy, rather than to try to make them our allies through artificial introduction or dissemination.

A large percentage of the timber injured by insects can be utilized which will, at the same time, without additional expense, contribute greatly to the control of insects which cause waste, and also prevent injuries and depredations in the future.

Under past conditions the poor management or neglect of the average forest has contributed to the increase of depredations by insects.

Under present conditions of better management of local forests and the more progressive manufacturing enterprises, considerable is being accomplished toward the reduction of losses, but in the average forest, and the average business enterprise dealing with forest products, present conditions are little better than in the past.

This is largely due to a lack of appreciation of the importance of the subject and failure to realize the opportunity and practicability of preventing a large per cent of the losses.

CONSERVATIVE TURPENTINING.

By Geo. B. Sudworth,
U. S. Forest Service.

NATURE OF NAVAL STORES.

Naval stores, so called, consist of commercial "spirits of turpentine" or turpentine, rosin, and tar. All are derived chiefly from the resin of pines, but may be derived also from that of such related conifers as the spruces (Picea) and the false hemlocks (Pseudotsuga). Pines gave these supplies in the early history of this industry, as they do now in both this and in European countries. Turpentine and rosin constitute the principal and most valuable products known as naval stores. Pine "tar" or "pitch," once the principal product and so extensively used for rendering marine vessels water-tight, plays but a very small part now in naval-stores production. The present term "naval stores" dates from the use of pine tar in the days of wooden and other ships.

REGION PRODUCING NAVAL STORES.

Naval stores are produced now almost entirely in the South Atlantic and Gulf States. Southeastern Virginia, eastern North Carolina, and South Carolina originally yielded this country's naval stores. They are produced now chiefly by Georgia, Florida, Alabama, Mississippi, Louisiana, and eastern Texas, but very little comes from the last-named State. The center of production is in Florida, formerly having long been in Georgia. The seat of greatest production is likely to be next in the region of Louisiana, Mississippi, and Texas, on which, after the exhaustion of Florida's pine forests, production must depend.

SPECIES OF PINES YIELDING NAVAL STORES.

The longleaf pine (Pinus palustris) and Cuban or "slash" pine, which are pitchy, hard-wooded pines, yield the naval stores of our commerce. Practically all of the other native pines are capable of producing naval stores, but they are not now worked. The near future will unquestionably see at least two or three other southern pitch pines added to the list of producing species, as well as one or two species of western pines. It is not likely that the "white" or soft-wooded pines will ever be resorted to as producers of naval stores.

HOW NAVAL STORES ARE OBTAINED.

GUM SPIRITS OF TURPENTINE AND ROSIN.

Naval stores were first derived by charring or burning the wood of pitch and other pines in rudely constructed pits or kilns. The product then was pitch only, because charring the wood consumed or liberated as waste the volatile turpentine. Naval stores are now produced by distilling the crude resin obtained from living longleaf and slash pines. The principal product, turpentine, is driven off in steam in a simple copper "still," the turpentine being collected with the water after condensation. The residue, cleared of all impurities by straining, is commercial rosin. No other products are yielded.

WOOD SPIRITS OF TURPENTINE.

Various patented processes, which subject the ground or otherwise reduced "fat" wood of longleaf and slash pine stumps, waste logs, and butts to steam or destructive heat applied to or in closed retorts, produce a form of turpentine, which, when refined, has practically the same commercial qualities as that distilled from crude gum or resin.

This means of obtaining turpentine is comparatively new and still subject to considerable improvement. The steam processes have so far produced a purer grade of turpentine than any of the processes which carry distillation to the point of charring the wood. Much of their products require redistillation to obtain a pure grade of turpentine; but they derive, in addition to turpentine, charcoal, and a residue of heavy pine-tar oil mixed with other ingredients not obtained by the steam processes. The charcoal is, however, practically a waste product, because usually it is too far from a market, while as yet there is very little profit derived from the sale of the heavy tar products.

SOURCE OF CRUDE RESIN.

PRELIMINARY DISCUSSION.

It seems probable that much of the production of naval stores will be dependent in the future, as it has been in the immediate past, upon the production of crude resin from living trees.

The utilization of the waste products of lumbering, such as stumps and other "fat" portions of the trees for the production of wood spirits of turpentine, appears likely to be carried at once to a proper degree of strict economical use. But the magnitude of this utilization depends rather upon the enormous lumbering waste of the past than upon that of any system of lumbering now in vogue or likely to be in the future. The supply of dead and down "fat" pine waste obtainable now is considerable, but it is clearly exhaustible within comparatively few years. No such supply can be looked for even in the immediate future, and certainly not in the distant future, both for the reason that the enormous supply of southern pine timber once available is now very largely lumbered out, and because the intensely conservative lumbering of the present and future will leave comparatively little for the wood distilling turpentine plant. The product, therefore, of wood spirits of turpentine can be safely put down as a small part of the country's total naval stores product. Production of wood spirits must then depend entirely upon the use of mill waste, and very much shorter stumps than old systems of lumbering are now affording. Mill waste yields approximately only about one-fifth as much turpentine as the heavy "fat" pine waste logs and high stumps which are worked entirely now for wood spirits.

HOW CRUDE RESIN IS OBTAINED.

The first method of obtaining crude resin was to cut a deep pocket or "box" in the base of the tree for the purpose of collecting the resin which flowed from cuts made in the tree's trunk just above the box. New cuts, "streaks," were made, one above another, each week in order to stimulate a fresh flow of resin, which dripped from the edge of the new cut "chip" into the box. The box held about three pints of resin, and at the end of every four weeks this was "dipped" out by means of a thin, flat, spade-like tool called a dipper.

The weekly chipping proceeded from March to September, when the resin would no longer flow readily. Each tree was usually worked, "turpentined," for four or five seasons, when it was abandoned.

At the end of four or five years the aggregate chipping done to each tree was equivalent to cutting off from two to six slabs (three-fourths of an inch to 2 inches deep) from two or three sides of the tree. The breadth of these slabs was from 8 to 12 inches and from 5 to 7 feet in height. Large trees were thus often practically stripped of their outer layers of living or "sap" wood. Moreover, the depth and width of the box was so great as to actually cut away from one-third to two-thirds of the tree's thickness at the base. The trees were thus so weakened that heavy wind storms easily threw them in large numbers. (See fig. 1.)

AREA OF PINE FOREST PRODUCING NAVAL STORES.

Originally the longleaf and slash pine forest, capable of, and in part, yielding the naval stores of this country, included southeastern Virginia, the coastal plain of North Carolina, South Carolina, Georgia, Florida, Mississippi, Louisiana, and the eastern border of Texas. (See figs. 2 and 3.)

But the area now producing naval stores is very much less, being confined practically to the extreme south border counties of Georgia, to Florida, to limited areas in southern Alabama, to Mississippi, to Louisiana, and to a considerably less extent to eastern Texas. Virginia's and the Carolinas' original pine forests, being nearly or quite exhausted, are now practically out of the producing belt, while eastern Texas forests, still largely intact, are really not yet in the producing belt. This is because of a prejudice among Texas timber-land owners against "turpentining" their pine, and also because they fear the added danger of fire to their timber, which must be specially protected in a turpentined forest. Their belief is that working the trees for naval stores reduces the market value and price of the lumber cut from such trees beyond all profit realized from the turpentine operations. The same belief is shared also by some pine-timber

owners in Louisiana and Mississippi. In the latter States this prejudice has prevented, until within the last five years, the rapid and complete establishment of naval stores production in that region. It is beginning to advance there now, through extensive combined lumbering and naval stores operations, and is likely within the next decade to become fully established throughout the longleaf pine belt.

The still quite general, unrelenting prejudice of Texas pine-timber owners is keeping the longleaf-pine forest of that region out of naval stores production, except in a few localities.

REGION OF GREATEST NAVAL STORES PRODUCTION.

Georgia, Florida, and Alabama, with Florida in the lead, now produce the bulk of our naval stores. Mississippi and Louisiana are next in point of production. Normally these five States, with Texas, should constitute the region of largest production. It is most probable, however, that the center of production, now in Florida, will move westward into the Mississippi River States. With the present generally wasteful methods of working the forests, this movement may take place within the next twenty-five years, or possibly sooner, owing to the present extremely rapid and exhaustive spread of the production in Florida.

CONDITION OF FORESTS PRODUCING NAVAL STORES.

Of the pine forest now yielding or being worked for naval stores 87½ per cent is being worked by the ancient, destructive box system. Twenty per cent of this timber is passing the point of production, while the remaining 80 per cent is at the height of its productiveness and will cease yielding within two years. Of this producing forest 20 per cent has been more or less burned, which means that the total possible production has not only been appreciably reduced, but that as a result of burning the turpentined tree trunks, the commercial quality of lumber available from this timber is also degraded. Charring the chipped or turpentined trunks produces extensive pitchy areas in approximately 8 to 10 per cent of the saw timber. The total loss from this damage is conservatively estimated at 5 per cent. It is believed to amount to from 5 to 10 per cent, for the damage involves 12 to 15 per cent of the best part of every merchantable tree.

It is estimated that 5 per cent of the forest, yielding or being worked for naval stores under the old box system of turpentining, is either dead or thrown down as a direct result of the severe cutting necessitated by this method. (See fig. 1.) This amount may be safely reckoned as total loss, since the scattered and isolated occurrence of areas so affected are not usually reached by lumbering operations before the timber is badly affected by decay and wood-boring insects.

The remaining 12½ per cent of forest yielding naval stores is being worked under an improved system of turpentining known as the "cup and gutter" or "cup and apron" method. No deep box is cut at the base of the trunk, and the turpentined pine trunks are injured only as a result of the season's chipping, which is on the whole as severe as that resorted to under the box system. The timber is, however, not in danger of being thrown by storm, because the trees are not weakened by deep boxes at their bases. This type of timber is relatively in thriftier condition than that worked under the box system, because it has received less injury. It is, moreover, as a rule unburned, for the reason that the intrinsic value of the cup and gutter outfit (liable to destruction by fire) compels greater protection against fire than is usually provided in the case of boxed timber.

PHYSICAL EFFECTS OF DIFFERENT METHODS OF TURPENTINING IN THE PAST UPON THE LIFE OF THE FOREST.

ANCIENT BOX SYSTEM.

Timber worked for naval stores under the old box system is more subject (1) to fire, from which may result death, or such injury of vitality that little or no product is yielded afterwards. From the severity of the box cutting large areas may be thrown by wind and be wholly lost; (2) under this system the forest is rendered unproductive of naval stores practically after the fourth year. Three to four years more of production may be added by cutting boxes on unused sides of the trunks ("back boxing"). The more enlightened operators who own their forests, and therefore value them, and expect to utilize the lumber after the first four years' use, for turpentining, refrain from "back boxing" to avoid the certainty of total or very great loss likely to follow from windstorms, which, as already shown, such over-boxed timber is too weak to withstand.

ALL YOUNG, AS WELL AS OLD, TREES ARE TURPENTINED.

In the earlier great abundance of naval stores producing pine timber only large trees were boxed. The young pole trees were left to grow. "Worked-out" timber was then quickly abandoned for new crops of "round" timber everywhere abundant.

The enormously depleted supply of round timber of to-day results in the boxing of practically every tree the land carries, down to 4 or 5 inches in diameter. This, too, frequently includes every tree. Profitable returns can not be expected from timber less than 10 inches in diameter. No young, unimpaired trees remain to form the future forest. The controlling purpose of this shortsighted policy is to strip the land as completely as possible, because in the life of the present operator another crop of naval stores is not expected. Young trees so severely boxed can not recover sufficiently to grow into thrifty, sound timber; they usually die. Possibility of profitable naval stores production in all sections so treated is either wiped out or will be within half a decade.

NEW CUP AND GUTTER SYSTEM.[a]

Timber worked for naval stores under the cup and gutter system, more conservative than the old box method, is—

1. Least subject to destructive fire, even when the usual annual "raking" is omitted. There are no deep boxes containing greater or less quantities of highly inflammable resin close to the ground, which, once fired, makes possible a burrowing fire at the base of the trees.

---

[a] The writer desires to make clear that the discussion here of the superiority of the cup and gutter system over the box method is not a criticism of other systems of turpentining which employ cups. Investigation of the cup and gutter system was begun some eight years ago as a means of abolishing the

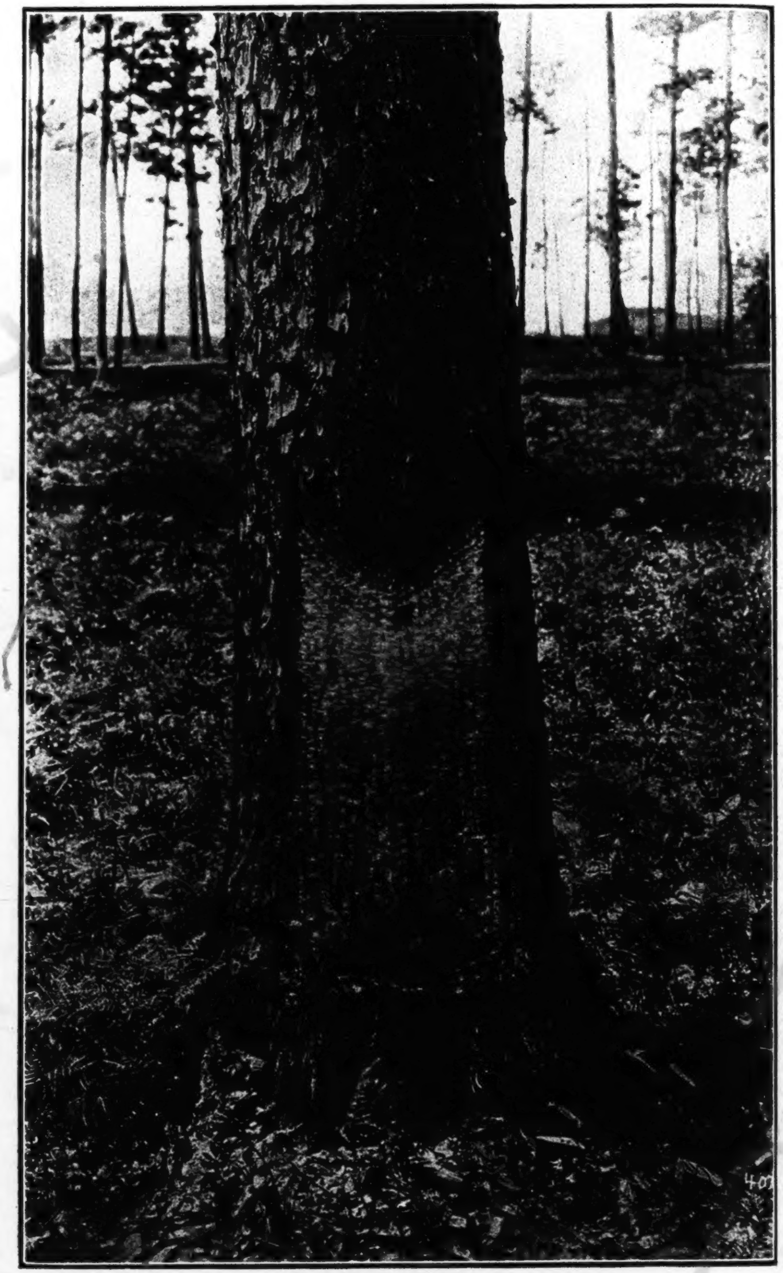

FIG. 4.—FACE OF SECOND YEAR BOXED TREE. NEAR OCILLA, GA.

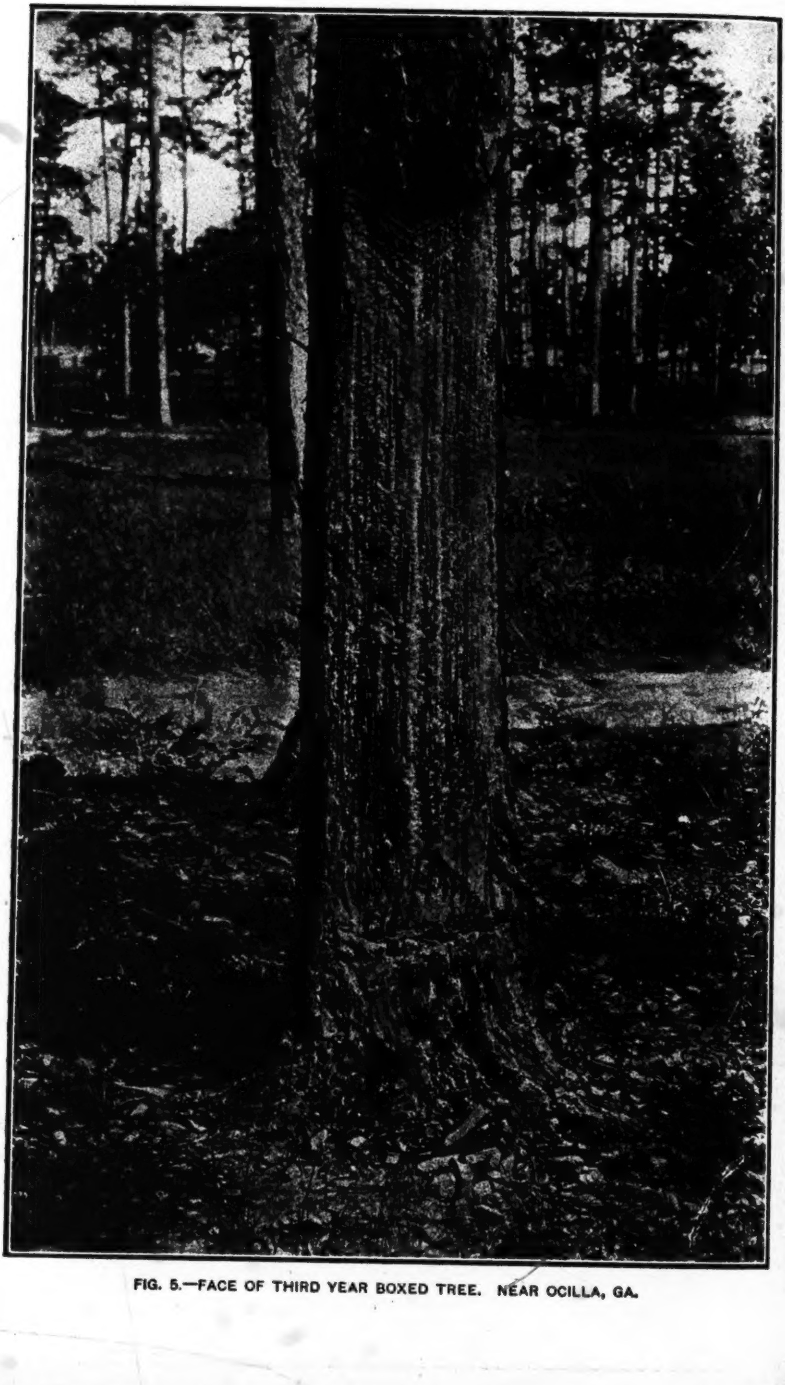

FIG. 5.—FACE OF THIRD YEAR BOXED TREE. NEAR OCILLA, GA.

2. The trees are not weakened by a deeply cut box, and hence not liable to be windthrown. With only a minimum injury from chipping, trees worked under the cup and gutter system maintain vigorous vitality during the period of production, while afterwards the trees continue to grow thriftily. Even very small trees so worked survive the strain and continue to grow rapidly afterwards.

On the whole pine forests "worked out" in part or completely under the cup and gutter system have undergone much less injury as regards their growing vitality than would have been the case had they been boxed. Ripe timber is in condition to be lumbered without loss by storm, while the younger trees are still in thrifty condition.

LOSS OF POSSIBLE PRODUCT UNDER ANCIENT BOX SYSTEM.

Naval stores production under the ancient system of boxing the trees is carried on at a loss of from 20 to 30 per cent of the possible total product. Moreover, the highest grade of rosin is produced by this method only during the first season.

The loss of product (extending over the four or five years of exploitation) is due (1) to undue evaporation (avoidable under a conservative method) of turpentine by long exposure of the crude resin, which must run farther and farther each season over the chipped face of the trees before reaching the box (see figs. 4 and 5). At the end of the first season the distance traversed by the resin is approximately 15 inches; second season, 30 inches; third season, 45 inches; fourth season, 60 inches. Evaporation is relatively greater each succeeding season, as the resin is exposed to the air for a longer time.

The loss in the quality of the product is measurable only in the grades of commercial rosin produced. Resin gathered from first year or "virgin" boxes yields the highest (whitest) grade of rosin. That gathered from second, third, and fourth year boxes yields lower and lower (darker colored) grades of rosin, which sell for lesser prices than the highest grade.

INCREASED PRODUCTION UNDER NEW CUP AND GUTTER SYSTEM.

The total loss of from 20 to 30 per cent of turpentine under the ancient box system of turpentining is saved by use of the new cup and gutter system. This saving is made possible—

1. By preventing the long exposure to the air of the dripping resin, which each succeeding season traverses a distance of not more than 15 inches of the

---

destructive box. The superiority of a cup system over the box was demonstrated by the Forest Service with the publication of Bulletin 40 and Circular 34. Since then other cup systems have been devised. The writer has no knowledge, based on actual use, regarding the merits of these systems compared with the cup and gutter system. The important principle of greater conservation of the forest's life and of the turpentine product was clearly demonstrated by the service's use of this particular cup system, and need not be redemonstrated for other cup systems, for the reason that in detailed working, cost of equipment, etc., there does not appear, in the writer's judgment, to be any features of the newer inventions which could increase the advantages, already brought out, of a cup system compared with the box method. For this reason the writer considers the comparative merits of cups and boxes sufficiently settled in so far as the principles of conservation are concerned. Of more immediate importance, as a source of greater conservation for the turpentine industry, has seemed to the writer to be the question of the shallowest chipping possible consistent with the greatest yield of resin.

tree's chipped face before entering a circular, impervious clay or metal receptacle. This is accomplished by moving the metal gutters (which catch and direct the resin into the receptacle) up to the cup at the end of every season.

Measurable gains in favor of this system also are the facts that less evaporation of spirits occurs from the smaller surface of resin exposed in the circular cup than from the larger surface of resin exposed in the box, and greater economy of crude resin is possible also in gathering ("dipping") resin from circular, smooth cups than from the rough boxes. Much resin is wasted in dipping from boxes, as well as in being imperfectly directed and caught in the boxes, while no resin is wasted when it is being directed into the cups or in collecting from cups. Practically all of the resin yielded by cupped trees is caught.

2. The loss in the quality of rosin made from resin of boxed trees is prevented in the case of cupped trees by causing the resin to run uniformly each season only a short distance into the receptacle. A longer exposure of the resin is found to account for the dark color of inferior rosins obtained from two, three, and four year boxed trees.

POSSIBLE CONSERVATION OF REMAINING FOREST BY USE OF IMPROVED METHOD OF NAVAL STORES PRODUCTION.

HOW LONG NAVAL STORES PRODUCTION WILL CONTINUE UNDER PRESENT METHODS.

It is estimated that naval-stores production would continue, under present methods of exploitation, for twenty-five to thirty years. At that time it is certain that from an industry of the first importance to the South it would sink to an inferior position. This conclusion may be safely founded upon the history of the production in Virginia, North Carolina, and South Carolina (now practically worked out). These States, once heavy producers, have retired from the field of important production, not to enter it again under present methods of exploitation. The States now yielding naval stores are necessarily meeting a much more intensive demand both for naval stores and for lumber (which must, in succession, come from the same forest) than forests of the exhausted States could possibly have been subjected to. It is even probable that present-day methods of exploiting naval-stores forests would bring the end in less than twenty-five years.

ATTITUDE OF NAVAL-STORES OPERATORS TOWARD PERMANENCY OF INDUSTRY.

Present-day naval-stores operators appear generally content to believe that continuance of their industry is coincident with the endurance of southern pine forests. The conviction is fixed that a given forest can be worked only four years, when new (round) timber must be sought for a continuance of operations. The end of this production is clearly conceived to be coincident with that of the virgin forest.

The idea of placing this industry upon a stable, permanent foundation by adopting a more conservative method of operating appears to have been but little thought of. To this end, the idea of adopting the cup and gutter system, a method of exploitation more conservative of the forest's life, in order that operations might not, as under the ancient method, destroy the trees, proved to be a most difficult undertaking for the Forest Service to propagate among operators, so fixed had become the belief that no method except the ancient one could be profitably employed. The accomplishment by the Forest

Service, through four years of incontestable demonstrative field results, of showing that the cup and gutter system should replace the old box method, was achieved against the deepest sort of prejudice and disinclination among otherwise intelligent operators to accept a new system for the one inherited so long ago. The argument had to be abandoned that, if the new system insured as great a return in naval stores as the old destructive method, it would be to the interest of timber-owning operators to apply this new, conservative method because, not necessitating the cutting of a deep basal box, it injures the trees far less than the ancient system. The idea alone of conserving the life of the forest, of leaving it in as thrifty a condition as possible after naval-stores production, found little or no support. Had it not been possible for the Service to show by actual figures of yield that the new system gives a return of from $1,500 to $1,600 per "crop" (10,000 trees) in place of about $1,000, the old method would still be in universal use, where now some 30,000,000 cups are used. (See figs. 6 and 7.)

Even with this overwhelming proof of what the new conservative method offers in money returns alone, there are many intelligent operators who will not abandon the old system. There is probably not another example to be found in the development of any industry in this country where regional prejudices is so strong against a change of old customs. It is believed, however, that ultimately the idea of maintaining highest conservation in naval-stores production and of placing this industry on a permanent basis can be made to prevail.

Economic conditions are such in the United States that the extremely conservative system of production prevailing in European countries can not be adopted here. The returns accepted there from a naval-stores forest are too small to attract the average American operator. The rate of production and the profit are comparatively much larger here and must needs continue to be in order to satisfy our social conditions. Our past lavish waste in producing naval stores must be reduced to the strictest economy in method of exploitation and in perpetuating, by full use, the life of naval stores producing forests.

WHAT IS ACCOMPLISHED IN CONSERVATIVE NAVAL STORES PRODUCTION AND IN LENGTHENING THE LIFE OF THE FOREST BY A NEW METHOD.

The Forest Service has established by incontestable experiments that the cup and gutter system of deriving naval stores—

1. Yields 30 per cent more product than the ancient method.
2. Does not so weaken the trees physically that they are in danger of being wind thrown.
3. Leaves the timber in thriftier condition because it has not been severely injured by box cutting.

The advantages accruing directly to timber-owning operators are much greater money returns (approximately 50 per cent more than from the old system), and insurance of the timber against destruction by storm before it can be lumbered. The fact that boxing leaves the timber in imminent danger of total destruction by storm has dissuaded not a few pine-timber owners from turpentining their forests at all. Such loss of profit to those people for want of a safe system of exploitation can now be obviated by adopting, if not the system shown to be most conservative, the cup and gutter system even with the old method of deep chipping, in place of the destructive box method.

WHAT MAY BE EXPECTED FROM A STILL MORE IMPROVED METHOD OF PRODUCING NAVAL STORES.

A still more conservative method has been discovered by the Forest Service, and its absolute practicability has been thoroughly established by experiments during the last three years on some 80,000 trees.

By this method it is calculated that—

1. A crop of trees may be worked continuously for 15 to 20 years, instead, as at present, of 4 years. At the end of this period the same trees may be worked for another equal term of years, provided the utmost naval-stores capacity of these trees needs to be made use of before lumbering.
2. From 22 to 25 per cent of turpentine (the naval-stores product of greatest value) is obtained in place of from 19 to 20 per cent yielded from present (old and new) methods.
3. The vitality of the trees worked is conserved in the very greatest degree, because the injury from chipping or tapping is reduced to a minimum. Little injury to the trees is a factor in the greater production of turpentine, because the trees being more vigorous, yield a continuously strong flow of crude resin. The greater injury of the trees worked under the older systems weakens their vigor and causes them to yield resin less and less copiously each succeeding year.

This system consists in the use of clay receptacles and metal gutters for collecting the crude resin, and the application of uniformly shallow chipping in place of the generally practiced deep chipping.

DISCUSSION.

The three exceedingly important points of economy in this method are: (1) Greatly increased term of operation; (2) greatly increased product; and, (3) the fullest possible conservation of the growth energy or vitality of the trees.

The high productiveness made possible and the practically indefinitely prolonged operation in one location are the principal factors sought in establishing permanent naval-stores production. Both factors are commercially attractive to the individual operator who must realize profit in his own lifetime. A permanent industry and the greatest conservation of the forest under naval-stores production are also directly effected.

DETAILS OF MOST IMPROVED METHOD.

It is possible now to prolong the working period in the forest without change of base, because the new method requires the cutting away each year of only from 3½ to 4 inches in height of the usable trunk, while in the older systems of chipping or tapping from 15 to 16 inches in height were cut away each season.

It has long been believed by operators that severely deep chipping each week must be resorted to in order to stimulate the fullest flow of crude resin. The Service's experiments have proven, however, that extremely shallow chipping gives the greatest possible flow of crude resin, while the crude resin from such shallow chipping yields a larger percentage (approximately 5) of turpentine than does the resin from deeply chipped trees.

DEGREE OF SHALLOW CHIPPING ACCOMPLISHED BY USE OF THE OLD "HACK."

By special training chippers can put very much shallower "streaks" on the trees each week than are commonly cut with the ordinary "turpentine hack." The best possible saving with this tool is something over one year in three, or nearly two years in four, thus extending the usual working period of a forest from four years to six years. Even this shallow chipping was, however, found to be unnecessarily severe. But the limit of perfection is soon reached for this ancient tool because, as in the use of the ordinary chopping ax, control of the cut is dependent entirely upon the personal skill of the chipper, and this can not be made as perfect as is necessary for the fullest economy in chipping.

HOW THE SHALLOWEST CHIPPING IS ACCOMPLISHED BY USE OF A NEWLY INVENTED HACK.

A new turpentine hack has been invented, through directions of Forest Service experts, which affords perfect control of the depth and width of the "streak" cut. The skill of the chipper is not, as in the use of the old hack, a factor in cutting a shallow streak with this tool. A uniformly shallow chip can be taken off, thus making it possible to treat all trees alike and to cut only enough to stimulate each week a full flow of crude resin. Limited experiments indicate that a full yield of crude resin may be obtained by chipping the trees only from three-eighths to one-half of an inch in depth, and in height only from one-eighth to three-sixteenths of an inch. The common practice is to cut a streak from 1 inch to 1½ inches deep and from one-fourth to one-half of an inch high each week.

An important feature of this tool is that, when it is fully perfected, it can be applied to the tree in practically the same manner as the old hack. This will make it unnecessary for chippers to acquire the use of a new instrument—a nearly impossible accomplishment because of deep prejudice among turpentine laborers.

This tool is not in use by turpentine operators, for the reason that, while the working principle of the invention is established, considerable experimentation is required to perfect the detail working of the tool. Moreover, the Service has not yet published the practical results of its study of shallow chipping. The publication and distribution of these results is to take place shortly. With full knowledge then of the special advantages offered by the use of a shallow cutting hack it is moderately certain that the Service's new and highly conservative method of turpentining will be generally accepted.

FURTHER CONSERVATION OF PRODUCT POSSIBLE BY NEW SYSTEM OF GATHERING CRUDE RESIN.

Studies by the Forest Service indicate that from 5 to 6 per cent more turpentine is yielded by crude resin gathered every two weeks than from resin gathered once in four weeks. When gathered once a month, the long exposure to the air results in an appreciable loss of turpentine by evaporation. The added expense of more frequent gathering is trivial compared with the percentage of profit gained by the increased yield of turpentine. These studies, only indicative now of probable results, must be carried further before a positive statement of the possible gain can be made.

INCREASED PRODUCT BY CONSISTENT USE OF ALL NAVAL STORES PRODUCING PINES NOT NOW EMPLOYED.

SOUTHERN PINES.

At present only two pines, the longleaf and slash pines, produce this country's naval stores. The Service's study during the past three years of the distinguishing characters of the resins of native pines shows that three more forest-forming pines of the South (loblolly, shortleaf, and Virginia pines) yield naval stores in quantities equal to those of the longleaf and slash pines. Two of these untried species, generally held by operators to be nonproducing, form large forests in the South Atlantic and Gulf States as far west as eastern Texas and northward into Missouri. Their use for this purpose would augment the country's present resources very considerably, and would, in addition, extend the industry into States never before yielding naval stores, and serve also to restore in some measure the industry to States which have ceased producing. It is impossible now to determine what percentage of increase this addition to the resources will add. With the very probable return, by encouraged natural propagation, of these untried pines to areas from which they have been lumbered—unquestionably a wise policy—a still greater naval-stores resource will certainly be added in the future.

WESTERN PINES.

Similar studies by the Forest Service have recently determined that the forest-forming western yellow pine yields naval stores in quality and quantity comparable with the standard longleaf and slash pines of the South. The addition of this tree, which forms extensive forests both in the Rocky Mountain and Pacific Slope States, as a producer will give to western United States a new industry, the value of which can not be adequately estimated. Development of it will require demonstrations by the Forest Service of a special method of tapping the trees and the amount of commercial product obtainable. This is a work distinctly for the Forest Service to undertake on a sufficiently large scale to show what may be expected in that region, which in topography and in the character of its resin-producing pine is so different from the South that the system of turpentining now practiced in the latter region will require special modifications.

FUTURE STABILITY OF NAVAL-STORES INDUSTRY.

Future stability of the naval-stores industry in this country depends upon three factors:

1. Complete application in all naval stores producing forests of the most conservative system of exploitation.

2. Use throughout the country of all naval stores producing pines.
3. Systematic working of forests for naval stores in coordination with lumbering operations.
4. Effective fire protection.

COMPLETE APPLICATION OF THE MOST CONSERVATIVE SYSTEM OF EXPLOITATION.

Experience of the last half century has shown clearly, in the case of Virginia, the Carolinas, and Georgia, that so wasteful and severely injurious a system of turpentining as the ancient box method results in exhausting the producing forest at such a rapid rate and in such a short period as to preclude all possibility of permanent naval-stores production under that system in any given region. Under such a short-sighted policy and system continuance of the industry is clearly a question, not of established permanent production throughout the regularly maintained forest of the country, as in the case of wheat and other staple productions which become fixed resources of certain sections of the country, but of how long the country as a whole will continue to produce naval stores. Continuance of production is then dependent chiefly upon how long the suitable species of virgin timber of the country will last.

The center of greatest production, beginning at the northeast part of the southern pine forest, has gradually proceeded southward in the Atlantic region to the working limit of this turpentine pine belt. The center of greatest production has, to be sure, gone southward with the development of the southern country, but its progression has been like that of a great and consuming forest fire. A stable industry—a resource—naval-stores production, has not been left along the line of its march. Like the forest fire, it has been transient, flourishing only so long as round virgin timber remained to feed the flames of its turpentine "stills." The timber exhausted—worked out—new stills sprang up farther and farther southward in the great pine belt. New centers of business activity were formed and those in the rear died out. The forest that once gave support is gone or depleted beyond profit for the turpentine operator using the old system. Just as the lumbermen of the Great Lakes pine belt have been forced to go to the untouched forests of the Northwest, so the naval-stores producer of the South has gone farther and farther southward. The Georgia operator is now in Florida, the center of greatest supply, where he is producing heavily. Soon he will be obliged to look westward to the end of the Gulf pine forest.

Production by so wasteful a method that permanency of the industry is impossible, and the end of production can be clearly seen, is inconsistent with the possible permanent development of one of the South's greatest resources.

Use of the most conservative system of turpentining is imperative, therefore, for two reasons:

1. To build up permanent local production wherever a wise forest policy for that section makes it advisable to maintain continuously naval-stores and timber-producing forest.

2. In order to prevent degradation, through the present too rapid exhaustion of existing old forest, of a first-rank industry to a position of unimportance.

Approximately 20 per cent of the sound timber of the South is still unworked for this purpose. Application to this timber of the latest improved system of turpentining will permit it to be worked for twenty-five to thirty years before lumbering, and will go far toward staying the present rapid and premature exhaustion of a great naval-stores resource. Continued local production, which is greatly needed for the permanent upbuilding of otherwise resourceless sections, will also be encouraged and eventually established.

USE OF ALL NAVAL STORES PRODUCING PINES.

Just as in the sphere of agriculture, there exists, for the sake of the highest economy in production for every region, the necessity of growing as many different kinds of useful crops as possible, so in the field of naval-stores production it is imperative that all producing pines and other conifers be fully exploited for this product. In bringing this about, the most important principle of industrial economy would be fulfilled—the utmost development and utilization of existing resources.

SYSTEMATIC WORKING OF NAVAL-STORES FORESTS IN COORDINATION WITH SUBSEQUENT LUMBER OPERATIONS.

Coordination of naval-stores operations with the lumber operations which follow is looked to but little at present in the exploitation of pine-timber forests capable of yielding two such valuable products. That by careful attention to the proper sequence of rotation of these industries in a given forest the fullest economy in productiveness can be practiced is not to be questioned.

The presence of apparently unlimited timber supplies for pursuing both industries independently has been sufficient justification in the past. Now, however, with greatly decreased supplies of naval-stores forests and enormously increased annual demand for the products of these forests, there is imminent danger of unwarranted waste of the forests' productive energy by inattention to the proper coordination of turpentining and lumbering operations.

A few owners of naval-stores forests are now combining in one continuous operation the production: First, of naval stores; and second, of lumber—the operation intended to strip the land, to make full and final use of the stand. Realization of fuller value from their ownings is the incentive for combining the two industries, just as the great steel manufacturers have come to realize fuller profits by owning and mining the coal they use in making steel. The principle aimed at, but not yet effected, is proper coordination in turpentining and lumbering operations—a combination of effort which is highly essential for practicing the utmost economy and deriving the fullest returns from a naval-stores forest.

Under the ancient method of turpentining much timber has failed of proper utilization for lumber after being worked out for turpentine, because lumbering was not planned to follow at the close of the turpentine work. At the present time many lumbering operations are crowding out, on too short periods of rotation, the production of naval stores or are neglecting it entirely. Both are unjustified in this period of greatest need for utilizing the fullest productiveness of forests. No data are available now to show comparatively the ratios of profit in lumbering naval-stores forests and in working them for this industry to the costs of property and of carrying on the two operations. It is believed, however, that relatively much greater returns are realizable from naval-stores operations. Certainly in the fullest economy of use the turpentine forest should be made to produce its fullest returns before ripe portions of the stand are lumbered. This, when properly coordinated with the subsequent lumber operations, will make greatly for the permanence of the industry.

With the accomplishment now of a highly conservative, and at the same time profitable, method of turpentining, all lumbering and naval-stores operations should, for the permanence of both the industries themselves and for the owner's profits, be so carefully coordinated that the lumber interests take up and use the turpentined timber only after it has been made to give its fullest returns of naval stores.

Future studies of the Forest Service are to determine whether or not its extremely conservative method of shallow chipping for turpentine may not be applied to half-grown or to large immature timber without actually checking its profitable annual increment of growth. Should it be possible in this way to work a comparatively young forest for naval stores up to maturity, the long period of naval-stores production sought now during mature life of the forest, will not hold the mature timber out of lumber operations so long beyond the point of mature growth.

EFFECTIVE FIRE PROTECTION.

A word only needs to be said regarding the relation which effective fire protection bears to the permanency of the naval stores industry. Ground fires are the naval-stores operators' greatest and most dreaded enemy. His equipment and "crops" of turpentined trees may be ruined by severe fires. At considerable expense the inflammable trees are protected at the end of every season by raking in a small circle about each tree. Even this does not insure complete protection, for many "crops" are then burned.

The turpentine operator is, therefore, in position to welcome effective state or national fire protective measures. He has come, however, through the apparently impossible enforcement of existing forest-fire laws, to depend upon the protection he himself provides. He prepares, as best he can, to meet the annual ground fires which "irresponsibles" set out. When it can be safely done he burns the grass himself to prevent others from doing it less carefully.

The naval-stores operator would not be inonvenienced if the forest were unburned. Owners of cattle ranged at large in Southern pine forests are charged locally with burning the forests every winter to improve (?) the grass (now only tough sedges which afford little nutrition, as evidenced by the extremely small size of pine-forest cattle).

CONSERVATIVE LOGGING.

By **Earle N. Clapp,**
Chief of Management, Forest Service.

MANNER IN WHICH MATERIALS ARE USUALLY WASTED.

To one who is familiar with woods work in the United States it is a matter of certain knowledge that in all cases the fullest possible use is not made of the timber cut, and that little thought is given to the question of future supply from areas which are being cut over.

The logging methods which have been used are in all cases the result of conditions. Very naturally a lumberman wishes to operate at a profit, and often he considers the timber supply inexhaustible. In some other cases carelessness and wasteful methods are due to the desire of the lumberman or foreman to avoid conflict with laborers, and very frequently prejudice concerning utilization is responsible for certain classes of waste. The great factors are, however, stumpage and market prices. It is obvious that the percentage of timber wasted in different regions, or even in the same region, and in logging different species, or even the same species, will vary greatly.

Utilization in European countries is much more complete than in the United States, and comparisons when made usually reflect upon operations in the United States. When it is considered, however, that stumpage prices for various kinds of wood in Europe are to-day from two to ten times as great as for the same class of material in the United States, the reason for closer utilization in Europe is obvious. It is decidedly encouraging, however, that utilization in the United States at the present time in some cases is nearly as close as market conditions and stumpage rates will warrant, and such cases are more numerous than ever before.

The reasons for the closer utilization of to-day are clear: Much of the available timber has been cut, and many of the better species, as, for example, eastern white pine, are nearly exhausted, and market prices for the manufactured product are such that the lumberman can well afford to cut low stumps, utilize timber well into the tops, utilize dead timber, and to remove from the woods much more of the merchantable material than formerly.

A casual examination of a cut-over tract gives very little idea of the amount of merchantable material which has actually been wasted. It requires a thorough knowledge of market conditions and a series of actual measurements to determine accurately the percentage of unnecessary waste in any operation.

MATERIAL LEFT IN THE WOODS.

The most wasteful method of logging is that in which all of the material cut is left in the woods. Cases of this kind have in the past been comparatively frequent, and even at the present time one occasionally sees lumber operations in which little or none of the material cut has been removed. It is not infrequent to find logging operations in which, because of weather conditions, only a partial removal of the timber is possible, and still more frequently it is impossible to remove material cut soon enough to prevent deterioration; for instance, in basswood operations in the North and Northeast, if the logs are left on the ground for a year discoloration of the sapwood follows at least. This reduces greatly the price which may be obtained for the manufactured product by diminishing the amount of lumber of the better grades. This, of course, in cases in which logging is delayed only one year, does not mean an actual loss of material, but loss through failure to utilize to the best possible advantage the material cut. While this kind of loss is exceedingly common, it is difficult to estimate its exact amount.

Heavy snowstorms are frequently responsible for the leaving of large numbers of logs in the woods. Whole skidways are covered and often lost track of, and in many cases it is impossible to return the following spring for logs and skidways which have been left. The fact that the loss in this manner differs frequently in different operations in the same region and under the same conditions shows that in many cases it is more or less due to carelessness. The leaving of lodged trees, while it seems infrequent in the average logging operations, is in reality responsible for a large loss, considering the cut of the whole United States.

In the early days immense tracts of lands in the eastern hardwood belt were cleared for agricultural purposes and the timber destroyed because no markets were available. While this practice is almost a thing of the past, the destruction of all the timber cut from agricultural lands sometimes occurs even to-day. More frequently sawmill men purchase the timber from such tracts at a specified rate per acre and utilize as much of the saw timber at they care for. All the remaining timber is cut and burned, and this in many cases amounts to a considerable waste. There is little excuse for this form of waste under present conditions, since hardwood stumpage for saw timber is now rarely selling for less than $5 per thousand feet b. m., and cordwood stumpage almost universally for $1 per cord.

BAD MANAGEMENT.

Badly managed logging operations are responsible for immense losses, which may include practically all of the classes of waste hereafter discussed. Very frequently the best means of transportation are not used. It is estimated, for instance, that if basswood logs are driven instead of being hauled to the mill by railroad that the loss in the manufactured product, under the most favorable conditions, is at least $2 per thousand. Because of poor management, removal of timber is frequently delayed unnecessarily, so that deterioration to a greater or less extent follows.

INFLUENCE OF OWNERSHIP.

Another factor which under very similar conditions influences greatly the percentage of waste in logging operations is whether the timber is cut by the owner of the land, the owner of the stumpage only, or under stumpage contracts. Frequently the actual sale of the land with the stumpage may mean careful logging and little unnecessary waste, while the sale of only the stumpage based upon a scale after cutting, or cutting under a stumpage contract, will be followed by very wasteful methods in order that the operator may assure himself of the maximum profits.

LEAVING OF INFERIOR SPECIES.

It has been the exception rather than the rule in the operations of the past for lumbermen to remove more than one or two of the most valuable species of timber from an area in one cutting. Take, for example, the history of logging operations in the Northeast. The first cut removed the white pine and a very few of the largest and best spruce; the second operation followed several years later, removing only the large spruce which was left; after another interval the third operation took out all the softwoods, regardless of size, which were suitable for pulp. In many districts the fourth logging operation is now in progress, and includes the hardwoods left from previous cuttings.

Forest Service Circular No. 118, "Second growth in the Southern Appalachians," gives another instance of first logging the more valuable species from a tract and later returning for other species. It states that many tracts in the Southern Appalachians have been logged at least three times during the last ten years. In the first logging only the poplar and white oak saw timber were taken; the next operation removed the oak timber suitable for staves, and the final logging operation removed the smaller and rougher saw and tie timber of all species. Poorer species still remain on the ground.

Considerable parts of the forests of the United States, particularly of the West, are made up of only two or three species. It is customary in such forests, where there is a great difference in the relative value, to cut only the better species, with perhaps a few of the very best trees of the inferior kind. The species left is so inferior and the stand so scattering that until market conditions and requirements change greatly it will be absolutely impossible to return. The Douglas fir and hemlock stands of the Pacific coast, and lodgepole pine and balsam stands of the Rocky Mountains are familiar examples. In the Douglas-fir forests on the coast it is not uncommon for lumbermen to leave from five to twenty-five thousand feet b. m. of merchantable hemlock to the acre, and this in most cases can not afterwards be logged.

Examples of a similar kind can be given for logging operations in other parts of the United States. While it is realized that logging of this kind is usually the result of actual conditions which would have prevented the removal at a profit of all species at the same time, and that the lumberman was therefore forced to conduct his operations as he did, it can not be denied that the economic waste through such methods is enormous. Usually the intervals between logging operations are so long that logging roads have to be reconstructed. It is not customary to follow the same course, and this means that a large amount of timber is cut for building roads. When the best species and the largest trees are removed many of the smaller trees and trees of inferior species are broken, and many more are cut to provide space for skidways and skid roads. The slash which is usually left burns in many cases, and causes great destruction in the timber. One of the greatest losses, and one often least considered, is that of the change in the composition of the forest. If the seed trees of the best species are removed it necessarily follows that the resulting reproduction must be of the inferior kinds.

The results in national forest sales show conclusively that inferior species may be taken in practically all logging operations. In a number of sales on the Manti Forest, in Utah, the total cut is made up of 91 per cent of the valuable Engelmann spruce and 9 per cent of the comparatively valueless white fir. On the Modoc Forest, in California, 5 per cent of the total cut in a number of sales is made up of white fir and 95 per cent of yellow pine. In a number of the sales on the Sequoia Forest, in California, 78 per cent of the total cut is made up of the valuable sugar and yellow pine, while 22 per cent is made up of the inferior white fir and cedar. Purchasers object in some cases to the inclusion of inferior species in sales, and there is more or less difficulty in marketing the product manufactured from such species. Even when inferior species are included, however, purchasers have finally been able to market the product and to compete successfully in the general market with lumbermen who are cutting from privately owned lands and who do not remove inferior species to any great extent.

LEAVING OF SMALL BODIES OF TIMBER.

It is the experience of nearly all lumbermen that small bodies of timber in comparatively inaccessible places are, as a rule, left when the area is cut over. In many cases such bodies of timber could be removed at a slight profit or without actual loss. If small bodies of timber of this kind were removed it would enable lumbermen to hold other accessible timber, and the rise in stumpage prices at the present time is so rapid that the gain would be considerable in most large operations. Generally, when small bodies of inaccessible timber are left it is impossible to go back after logging is completed and the camps are taken out. Contracts for the sale of timber on the national forests provide against this form of waste and require purchasers to remove such bodies of timber, sometimes even at little or no profit, since such removal means an economic gain to the country as a whole. Such features are, however, provided for by just stumpage rates for the whole sale.

ONLY ONE CLASS OF MATERIAL TAKEN.

Lumbering operations in which only one class of material is removed from the forest are not uncommon. In cases where this material is saw timber the waste may not be excessive, but in other operations in which, for instance, only hewn railroad ties are utilized, much merchantable timber is necessarily left. Of course stumps can be cut low in most species, but the utilization in the tops is not as a rule complete. The greatest loss when ties are cut is perhaps owing to the fact that only trees of certain size, from about 11 to about 17 inches in diameter, can be taken; in other words, the young and thrifty trees of most species are removed from the stand, while the mature and slowly growing trees are left. These mature trees in many cases will be a partial or entire loss before the area in question can be cut over a second time.

Another illustration of great waste, owing to the utilization of only certain products, is in the shake business of the Sierras. Only the sugar-pine trees which split easily can be taken. This means that many trees, even though felled, must be left. Since only the straight grained, clear part of the trees can be taken, all material in the tops must be wasted. Fortunately, however, this form of waste is largely a thing of the past.

LEAVING OF DEFECTIVE AND DEAD TIMBER.

In the usual logging operation a large number of the trees which are only partially merchantable are not removed. For instance, it is found in many of the sales on the national forests that a considerable percentage of the trees in the stands may contain only one merchantable log, and that this log may be cut and removed at a slight profit or without actual loss. The prejudice against the use of dead timber is also responsible for a large percentage of loss in most lumber operations. Contracts in all sales from the national forests provide that the purchaser shall remove merchantable dead timber. In a number of sales in Utah, which include both dead and living timber, 10 per cent of the total cut was dead timber, and for a number of sales in Colorado and southern Wyoming 20 per cent of the total cut was dead timber. This, of course, is an addition to the large amount of dead timber sold in the sales including only dead timber. It is a matter of great interest that in some forests at the present time 40 per cent of all the timber which is being removed is dead. Defective trees which contain one or more merchantable logs and dead timber, if not removed during the first logging operation, are almost certain to be a total loss.

BEST TREES AND SPECIES USED FOR CONSTRUCTION.

Until the past few years it has been the practice in practically all lumber operations to use the best species of trees, and even the best trees, for various construction purposes, such as camps, road making, etc. In almost all cases poorer trees of the better species and trees of inferior species have been available. It is true that in some cases they are not quite as suitable for construction purposes as the better species and trees, but it is certain that the profit in logging operations in the long run is greater by using poor trees for construction purposes. Specific examples of this class of waste are the use of spruce in the Northeast, where balsam and inferior hardwoods are available; the use of good trees in the Southern pine district, where in almost all cases poor specimens are at hand; the use of lodgepole in the

Rocky Mountains, where balsam could well be used; and the use of Douglas fir in the West and Northwest, where hemlock is left on the ground in most logging operations.

USE OF SAW TIMBER FOR FUEL.

The market prices for various classes of material in the United States at the present time, even though they may seem good, are not yet high enough to insure the utilization of all classes of material to the best possible advantage; for instance, during the summer of 1908 one concern in the Northwest bought the best grade of Douglas fir flooring logs and worked them into cord wood. The reason for this was that it was cheaper to buy the clear, straight-grained logs which split easily than to buy at reduced prices and cut up the knotty and inferior logs of lower grades. The practice of utilizing valuable saw timber for cord wood has also been quite common in parts of the Rocky Mountains and in the eastern hardwood district.

USE OF BARK ONLY.

It was formerly the practice, in order to obtain the supply of hemlock bark demanded by the markets, to cut hemlock and utilize the bark, leaving the logs to decay. In northern New York, for instance, for a period of from twenty to forty years the demand for saw timber was so slight and the price paid for hemlock timber in particular so low, averaging about $4, that it was impossible to handle the timber at a profit. For the bark, however, there was a good demand and high prices could be obtained. The amount of waste was obviously enormous when it is considered that the amount of saw timber to a cord of bark is about 1,000 feet. The same practice was carried on in the hemlock regions of southern New York and Pennsylvania.

Under present conditions the bark of chestnut oak is more valuable for its tannin than that of hemlock, and occasionally the practice of cutting chestnut oak and utilizing only the bark is followed in the Appalachians. The total amount of timber wasted in this manner is, however, comparatively small.

HIGH STUMPS.

In practically all old lumber operations stumps were cut excessively high, and while present practices are a great improvement, there is still much unnecessary waste. In old cuttings in the East and in those parts of the West in which the forests are made up of small trees, stumps of 7 or 8 feet are not uncommon in winter cuttings. The reason for this is obvious when the expense of shoveling away the snow from the trees is considered. In summer cuttings, stumps 2½ to 4 feet are not uncommon. For this waste there is no good reason. In the Northwest in practically all of the cuttings of the past spring boards were used, and fir and cedar stumps as a result will average at least 5 feet in height. In this region spring boards have, however, been practically done away with, so that fir stumps are now cut to about 3 feet and cedar to 3½ feet. It is perfectly feasible to reduce the height of fir stumps to about 22 inches and that of cedar, except in the case of defective trees, to about 30 inches. This makes an average loss of at least 6 inches in each tree cut at the present time, which in the aggregate is enormous.

Every lumberman acknowledges that, except for defects, the best quality of lumber in the whole tree is found in the butt log, and therefore, in addition to the actual quantity of timber which is wasted in cutting high stumps, the quality of timber must also be considered.

Some examples of good results now being obtained are of interest. On the national forests, contracts in the Rocky Mountains and Sierra regions provide for cutting stumps to a maximum height of 18 inches, except in special cases, and further provide that the height shall be less if possible. It is reported that in Michigan, in some of the white pine cuttings, stumps are being cut level with the ground. It is commonly known that black-walnut timber is taken down below the ground level by digging around the tree and cutting the roots.

It is decidedly interesting to note the effect of the contract requirements of national forest sales on operations on private lands. One specific instance in western Montana will serve as an illustration. A company logging on its own lands commonly cut yellow pine stumps between 2 and 3 feet. After purchasing timber from the national forests, however, and cutting the stumps 18 inches and lower when possible, the company in question is now requiring the cutting of low stumps on its own lands.

TOPS.

In many logging operations of the past (but rarely at the present time) it was the common practice to take only clear logs and to leave all the knotty logs of the top on the tract. Gradually, however, as market prices have risen, the diameter limit to which trees can be utilized has decreased, until now in the spruce forests of the Northeast private companies utilize spruce and balsam to about 4 inches diameter. In the pine forests of the South logs are commonly taken to a diameter of 10 or 12 inches. In the lodgepole pine and Engelmann spruce forests of the Rocky Mountains cutting on private lands commonly utilizes tops to 8 inches; in the Sierra forests and Douglas fir forests of the Northwest timber on private lands is not commonly cut to a lower diameter than 15 to 20 inches. The contracts in sales from the national forests of the Rocky Mountain regions commonly require purchasers to utilize timber to 6 or 7 inches for saw timber when the logs obtained may be manufactured into merchantable material. The sales from the Sierra and coast forests require purchasers as a rule to take merchantable material to a diameter of 10 inches. Where there is a market for mining material, however, utilization to 8 inches is required. Trees are used for cord wood to 3 inches.

A source of great waste in logging operations throughout the United States has been the fact that tops below saw timber size have not been made use of. In many cases market conditions are wholly responsible for this. In others, it would be possible to utilize tops to a diameter of 2 or 3, or at most 6 inches for some such purpose as cord wood or the manufacture of charcoal.

LOG LENGTHS.

In the usual logging operation on private lands little attention is paid by superintendents and foremen to the question of varying the lengths of logs cut. In almost any logged-over area pieces of merchantable material 8 or 10 feet in length may be found when it is the practice to utilize logs as short as 12 or 14 feet. By properly varying the length of two or more logs all of the timber in most cases might have been saved.

As market prices for lumber increase, foremen and superintendents and owners of stumpage are more and more insisting that log lengths be varied to utilize fully the timber in tops of trees, and that log lengths be varied also in order to obtain the best grade of timber which is cut; for instance, by a proper selection of log lengths bad crooks may be avoided; still another instance is the occurrence of defective places in logs, which may be cut out altogether by a proper selection of lengths, and the amount of merchantable material obtained from the tree as a whole may be often increased by 25 per cent.

The question of cutting logs and lumber into both even and odd lengths has been discussed so frequently that it is unnecessary to go into the subject at this time. If market conditions allowed the cutting of logs into odd lengths, it would be possible to vary log lengths in the woods sufficiently to take much better advantage of defects and crooks, and thus secure the maximum amount of lumber of the best grades. It would also be possible to utilize more merchantable material in the tops.

TRIMMING LENGTHS.

Contracts for the sale of saw timber from the national forests provide in most cases that a certain maximum length shall be allowed for trimming. In logs of less than 30 inches in diameter 2 or 3 inches is usually a sufficient length for trimming; above 30 inches from 4 to 6 inches may be necessary. These figures apply to ordinary conditions, and in cases where logs are to be driven long distances in bad streams, it is frequently necessary to allow greater lengths. From 4 to 6 inches should, however, be sufficient for small timber even in very bad streams.

Some firms allow trimming lengths of from 8 inches to over a foot. This means that over 5 per cent of every 16-foot board is wasted in trimming at the mill. It is, however, difficult to estimate in private operations the average loss per log through excessive lengths for trimming, but it is common knowledge that in most cases lumbermen are careless in checking this waste. It is certainly very conservative to estimate the unnecessary length on all saw logs cut as from 3 to 4 inches.

SHORT LENGTHS.

In most regions common usage, present forms of machinery, and popular prejudice are responsible for the nonutilization of short lengths of logs. In the Rocky Mountains logs are rarely cut shorter than 12 feet, and in most operations lengths of 14 and 16 feet are preferred. In the Northwest 16 feet is considered a very short length and longer lengths are preferred. In the Sierras 14 feet is the minimum length, while 16 and 18 feet are the shortest lengths to which logs are cut in most operations. In the Southwest logs in a few operations are cut to a minimum length of 12 feet, while in rare cases lumbermen may cut to 10 feet; as in the Rocky Mountains, however, 14 and 16 feet are the common minimum lengths. In the pine forests of the South a minimum length of 10 feet is unusual, and logs are commonly cut 12 feet or more. In the hard-wood forests, with the exception of hickory, pulp material, mine props, and stave and heading blocks, logs are not cut below 8 feet in length.

In the Adirondacks 4-foot pieces are now used for pulp, and in New England spruce for pulp is frequently cut to 10 feet.

The following gives an idea of the minimum lengths of timber of various grades and the lengths which can be utilized for various purposes. These data indicate at least that log lengths could be reduced considerably for many species:

Cypress.—Tank, clear, select, shop, 10 to 20 feet; shorts in clear and selects, 12 inches to 8 feet; finishing, 10 to 20 feet; flooring, ceiling, drop siding, molded casing, and base or short lengths, 10 to 20 and 4 to 8 feet; turning stock, 18, 20, 22, 24, 26, 28, 30, 32, 34, 36, 42, and 48 inches; common lumber, 10 to 20 feet; pickets, 2 to 4 feet; car siding, 8 and 10 feet; car roofing, 5 and 6 feet.

Bay poplar (*Tupelo*).—Flooring or ceiling, 6 to 20 feet; bevel sidings, 10 to 20 feet; drop siding, 10 to 20 feet; box boards, 12 to 16 feet; clears, 10 to 20 feet; No. 1 common, 6 to 20 feet; No. 2 common, 4 to 20 feet.

Douglas fir (*coast*).—Flooring—vertical grain, 6 to 16 feet; flooring—flat grain, 10 to 16 feet; ceiling, 10 to 16 feet; partition, 6 to 16 feet; porch decking and ceiling, 4 to 16 feet; drop siding and rustic, 10 to 16 feet; stepping, 6 to 16 feet; finishing, 6 to 16 feet; windmill stock, 10 to 40 feet; battens, 8, 16, 18, and 20 feet; common boards, 6 to 20 feet; joist and scantling, 6 to 32 feet; bridge stringers, 32 feet and under; car sills, 34, 35, 40, 41, 45, 46, and 50 feet; timbers, 32, 44, 51, 55, 56, and 60 feet.

Spruce (*coast*).—Finish, 6 to 16 feet; thin finish, 6 feet and up; flooring and ceiling, 10 to 16 feet; wainscoting, 4 to 6 feet.

Southern yellow pine.—Common boards, 10 to 20 feet; fencing, 10 to 20 feet; dimension, 10 to 20 feet; heavy joists, 10 to 24 feet; timber, 10 to 32 feet.

Redwood, 3 to 5, 6 to 9, and 10 to 20 feet.

White ash.—Poles, 12 feet long; handles, 38 inches long.

Ash.—Scythe snaths, 5½ feet long.

Elm.—Sleigh runners, 16 feet long.

Fir (*Douglas*).—Bobsleds, 12 feet; grain tanks, 18 feet long; hay stackers and sweeps, 18 feet.

Hickory.—Axles 12 inches, bolsters 6 inches, bolster stakes 20 inches, doubletrees 52 inches, eveners 4 feet, handles 42 inches, butts 42 inches long, neck-yokes 50 inches long, oxbows 5½ feet, singletrees 38 inches, spokes 30 inches long.

Maple.—Axles 6 feet long, bobsleds 4 to 8 inches and 7 feet, harrows 14 feet, sleigh beams 4 feet long.

Oak (*white or red*).—Bolsters 6 inches, poles 12 feet long, reaches 12 inches.

Oak (*red*).—Bottom cleats 9 inches, brake woods 6 feet.

Oak (*white*).—Bolsters 6 inches, bottom cleats 4 feet 9 inches, plow beams 7 feet long, plow and cultivator handles 60 inches, plow standards 28 inches, poles 12 feet, reaches 16 inches, sand boards 2 inches, spokes 30 inches long, tongues 12 feet long.

Pecan.—Oxbows 5 feet long.

Pine (*longleaf yellow*).—Poles 12 feet, pole (stock grade) 16 feet, harrow eveners 17 feet, hayloader parts 16 feet.

Pine (*long and short leaf yellow*).—Stub tongue 12 feet.

Poplar.—Wagon box boards 16 feet.

BREAKAGE.

The amount of breakage in felling varies greatly in different operations in the same region and with different species. Much of course depends upon the roughness of the ground and sometimes also on weather conditions; as, for instance, in very cold weather the breakage of many species is materially increased. Carelessness is responsible for quite a large portion of loss through breakage. Here again the position taken by the logging foreman may materially increase or decrease the amount of loss, and much depends upon the experience of the men actually engaged in the work. In some operations there is a considerable percentage of loss through improper notching of trees which are to be felled and the splintering which follows. The damage which is done to young growth through careless felling is probably least often considered, and it is certain that the damage to future crops from this cause is very great. No other result can, however, be expected when so few lumbermen are cutting with a view to a second crop.

In logging operations in which it is necessary to use chutes the breakage is often considerable from poorly constructed or poorly operated chutes.

AXES V. SAWS.

In practically all of the lumbering operations of the present time the saw has displaced the ax for felling and cutting. Formerly, however, it was the practice to use the ax almost altogether. In cordwood operations the use of the ax is still common, and the resulting loss is just as great, if not greater, than in a saw-timber operation, because cordwood is cut into shorter lengths.

DONKEY ENGINES.

In some parts of the West the destruction of quite a large percentage of the timber which is left may be attributed to the use of donkey engines in logging. Wire chokers are slung on young trees, which are usually so badly damaged as to be worthless. Many other trees which are left are seriously barked by the use of cables, and drag ways are selected with no thought for the protection of reproduction.

DAMAGE IN SKIDDING AND HAULING.

While it does not decrease the amount of merchantable timber in a logging operation, the damage to young trees through barking in the skidding or hauling operation must be considered because of its relation to future cuts. Such wounds, if serious, result in killing a tree altogether, or in other cases allow infection by fungi, so that before a second operation the tree becomes partially or wholly worthless.

LOSS IN DRIVING.

Although the use of logging railroads is fast taking the place of driving, in some parts of the North and Northwest the drive is still common. In logging operations, which include only spruce, 1 per cent of the amount driven may be considered a legitimate loss. In operations which include pine, either the white pine or Norway pine of the North or the southern pine, 10 per cent on the average may be considered a legitimate loss. In driving, of course, much depends upon the age and quality of the timber; for instance, old timber floats much better than young timber in which the amount of sapwood is proportionately large; defective timber becomes water-soaked much quicker than that which is sound, and the loss is, therefore, correspondingly greater. The surveyor-general of the second district in Minnesota, in which district 90 per cent of the timber cut is driven, estimates that 5 per cent of large white pine is lost in driving; that an average of 10 per cent of small white pine and spruce and large Norway is lost, and that the loss in tamarack, balsam, and small Norway will average 15 per cent. The use of logging railroads obviously does away with all loss which results through driving. Another kind of loss must, however, be considered—that of the use of ties. Ties used in logging operations are rarely removed, even though they are sound when the steel is taken up. It is true that many of the ties used in such an operation are made from inferior trees, or inferior species of trees, but, on the other hand, it is very common to use for ties many of the young and thrifty growing trees which might be left to good advantage to form the basis for a second cut.

INDIRECT LOSS THROUGH FIRE.

Practically all of the lumbermen of to-day are cutting in such a way as to obtain a maximum present profit, and are not considering conservative forest management or even a second cut. It is natural therefore that all slash and débris should be left without consideration of protection of the cut-over area. Upon such cut-over lands it is quite certain in most regions that fire will follow. This fire in addition to destroying the slash destroys the greater part of the merchantable timber left, practically all of the young and thrifty growing timber which has escaped the lumbering operations, and what is worse, destroys practically all of the reproduction and in many cases seriously damages the soil itself. Many years must elapse before such fires are followed by even scattering seed trees and, in extreme cases, it is certain that several hundred years will pass before the soil is in any condition to produce even an average crop.

The proportion of cut-over lands upon which fire follows logging operations varies considerably with the species involved. In the eastern white pine belt practically all of the cut-over lands are burned over sooner or later. Upon the greater part of such lands reproduction of the valuable species at the present time is coming in very slowly, because of the comparatively small number of seed trees which have escaped. In the spruce belt of the Northeast, it is estimated that approximately 25 per cent of the lands cut over for saw timber and 50 per cent of the lands cut over for pulp have afterwards been burned over. In the southern pine belt fire follows cutting in almost every instance. The damage to the remaining trees is not, however, so great as in the North and Northeast, and even reproduction, after it has reached a height of from 3 to 10 feet, usually escapes.

In the coniferous forests of the Rocky Mountains and the west coast fire also follows cutting in almost every instance, and the damage in such forests is usually very great, sometimes killing practically all of the trees which have been left in the lumbering operations. In the hardwood regions fire probably follows lumbering much less frequently than in coniferous forests.

While the damage from fire on cut-over areas is only an indirect result of logging operations, the amount is almost beyond comprehension. As has been stated, fire not only destroys the trees and reproduction which have been left, but also seriously damages in many cases the soil itself. As a general rule, such fires extend beyond the cut-over areas and do a great amount of damage to virgin forests.

INDIRECT LOSS THROUGH WINDFALL.

In some parts of the country the damage through windfall which follows lumbering operations is serious enough to be considered. In New England it is estimated in some cases that such injury, when the cutting has been very heavy, exceeds that done by fire. In other parts of the United States the damage through windfall may consist only of the blowing down of isolated trees and the loss may be comparatively small. Trees blown down in this manner are usually a total loss, since cutting operations have usually been so heavy that it will not be possible to return for a second cut before the windthrown tree has become unmerchantable.

It is the custom in some parts of the United States to transport logs a part of the distance to the mill from the cutting area by rolling them down steep slopes. This practice, while it is very local and relatively of small importance, results in the destruction of practically all of the trees and reproduction in narrow strips.

REPRODUCTION AND FUTURE CROPS.

Since the lumberman is not, except in special cases, considering conservative forest management or even a second cutting, it is natural that he should not insist upon protection of the trees which are left and of reproduction. Reproduction in most cases suffers in almost every phase of the logging operation. The tree is felled, skidded, and hauled regardless of the number of young and thrifty trees which will be damaged. Young and thrifty trees of the valuable species are cut for various kinds of construction purposes, when inferior trees or dead timber are just as available and could be used at a slightly increased cost or at a slight disadvantage. It is exceedingly difficult, if not altogether impossible, to estimate the loss to future cuts through disregard of young growth. Indirectly the ultimate loss may be arrived at through the longer time required to produce a second cut. When, in addition to the direct damage to young growth in logging, fire follows as a result of the slash left, the result is much more serious. Under conservative methods a second cut in, for instance, the Northeast could be provided for within fifty years. If, however, the protection of reproduction is disregarded and fire follows a lumbering operation, it may be necessary to wait two hundred to three hundred years or even much longer to obtain a second crop.

Although the actual present loss of reproduction from any area seems of small importance, the economic loss in such cases probably far outweighs the loss through the other forms of wasteful methods already discussed.

The practice of cutting valuable species and leaving the inferior species for seed trees upon an area is also decidedly objectionable when the future crop is considered. Such practice makes it certain that the second crop of timber will be made up chiefly of inferior species, with only a small proportion of the more valuable species which form the present stand.

In the Rocky Mountains and in some parts of the Sierra and coast regions a very heavy cut and the destruction of existing reproduction sometimes result in a stand of chapparal in which it will be exceedingly difficult to bring about forest reproduction. In other parts of the West where reproduction is very light, it is probable that parks will be formed, and in many cases that the existing parks will be enlarged through the removal of too great a portion of the stand and the destruction of reproduction. The grazing upon such parks will, of course, be valuable, but present conditions indicate that the demand for and profit in timber will be greater than the demand and profit for grazing lands.

When we consider the fact that through the careless methods of to-day we are either delaying second and future crops of timber and providing for crops of inferior trees, or perhaps destroying almost all chance for future timber growth, the importance of carefully protecting all young growth is most clear.

Because of the comparatively high prices for lumber, the operator of to-day is in many cases removing trees of small diameter which are just about entering the period of best growth.

Data collected by the Forest Service show that with all species and with all market conditions there is a definite diameter limit, varying in each case with conditions, below which trees can not be cut and removed at a profit.

The following table from Forest Service Bulletin No. 73 shows the actual value of the material cut from yellow poplar trees of various diameters. The data were obtained in mill-scale studies which took account of both quality and quantity of the material produced. In the region in which the studies were made the cost of the logging was approximately $15 per thousand feet, board measure, and accordingly trees smaller than 19 inches in diameter could be logged only at a loss. On trees of 19 inches in diameter the profit, which increased rapidly for larger sizes, was only 34 cents for the thousand feet:

Values of yellow poplar—Virginia, 1905.

Diameter breast-high.	Amount sawed out.	Value per tree.	Value per thousand board feet.	Diameter breast-high.	Amount sawed out.	Value per tree.	Value per thousand feet.
Inches.	*Board ft.*			*Inches.*	*Board ft.*		
13	104	$1.38	$13.27	23	590	$10.61	$17.98
15	171	2.31	13.51	25	761	14.90	19.58
17	246	3.43	13.94	27	948	19.80	20.89
19	341	5.23	15.34	29	1,170	26.22	22.41
21	455	7.53	16.55	31	1,386	32.74	23.62

II. LOSS IN GIVEN OPERATIONS.

Very little data to show the actual amount of material unnecessarily wasted have been collected, some of which are incomplete and do not apply to the conditions of to-day. Practically all of the data given have been collected by members of the Forest Service. In each case these data show not the total waste, but the material which under existing conditions could have been utilized, that is, the unnecessary waste. As previously stated, perhaps the most important part of the waste—the destruction to young growth—can be estimated in the difference of time required to obtain second and future crops under the usual and conservative logging methods.

LOGS.

The following data collected in the year 1899, taken from Forest Service Bulletin No. 26, show the waste in spruce saw-timber logging:

(1) Percentage of entire cut wasted through the cutting of needlessly high stumps, 2.

For every 100,000 standards cut 2,000 standards were wasted because of needlessly high stumps. On a tract of 100,000 acres, with an average stand of 15 standards to the acre, the stumpage valued at 40 cents, the actual loss according to these measurements would have been $12,000.

(2) Unnecessary loss through leaving tops which might have been utilized, 6½ per cent of the total cut. It is estimated, however, that the actual value of the material wasted in tops averages only one-fourth as much as that left in high stumps.

(3) Unnecessary loss in building skidways which were not afterwards removed, about one-fourth standard per acre, or 1½ per cent of the total cut in a stand of 15 standards to the acre.

(4) Loss in building roads not estimated, since trees generally used were small and not merchantable under existing market conditions.

(5) The injury done in skidding was mostly to young growth, unmerchantable under existing market conditions, and an estimate was therefore impossible.

(6) Injury done in hauling included the cutting of spruce on steep hills. Although trees of all sizes were cut, the greater part were so small that an estimate of the waste could not be made.

Thus making a total loss of 11 per cent, as follows: (1) 2 per cent; (2) 2 per cent, 6½ per cent, and 1½ per cent; (3) 1½ per cent; (4), (5), and (6), taken together, 1 per cent.

This estimate does not include the sound logs left in the woods and lodged trees which were not felled.

The following data taken from the Forest Service Bulletin No. 30 show the difference in the amount of material obtained when cutting is done by ax or saw. The tree taken, if cut with the saw, would yield 1.26 standards; if, on the other hand, it were cut with the ax it would yield 1.19 standards, making a loss of 0.07 of a standard by using the ax. This loss is equal to one-half of 1 per cent of the total amount obtained by using the saw.

The following data are taken from the Department of Agriculture Yearbook for 1905: "Waste in logging southern yellow pine." The timber in this case was cut by a lumber company which had bought the timber from a land company, with the provision that payment be made upon the basis of the scale of the timber actually removed.

These measurements were taken in the year 1904, and are a fair indication of the amount of waste in southern pine operations at that time. All the measurements given were taken after logging apparatus had been removed from the cut-over land, so that there was no possibility of returning for the timber left. Measurements covering 300 acres show that more than 6 per cent of the large trees left standing after logging was completed was defective, which in all cases contained one or more good logs. Further measurements showed that of a total number of small and thrifty trees which were considered unmerchantable because of their size (trees below 17 inches at the stump) and were therefore left, 25 per cent was broken, knocked down, or in some way incapacitated for further growth, due almost entirely to careless logging methods. Of the total number of sap trees destroyed by logging it was found by actual count that one-fifth were cut for skid poles. In a stand which would average 10,000 feet b. m. to the acre of merchantable timber the amount of waste in tops per acre was 667 feet and the amount of unnecessary waste in stumps averaged 218 feet. Eight and eight-tenths per cent therefore of the total stand was unnecessarily wasted in tops and stumps. In addition it is estimated that in the ways indicated above 13 per cent of the total cut was wasted in merchantable trees left uncut and in merchantable material cut and left.

The following data taken from the report of the forestry commission of Maine for the year 1896 show the waste in cutting saw timber and pulp. The Maine rule was used in taking the necessary measurements, except as indicated.

In one case in which utilization was thought to be conservative, Mr. Cary, the author of the article, says that 36 per cent of the material on the tract was utilized, 47 per cent was needlessly wasted, and 17 per cent was left to grow. Measurements taken on the Kennebec River showed that 33⅓ per cent of the trees actually cut was wasted in stumps and tops, and Mr. Cary further states that this is a good average for the region at the time the cutting was done.

Another series of measurements showed that 71 per cent of the merchantable contents of the trees cut was utilized. In this case, however, men were cutting from their own land, and naturally logged more carefully than if the work were being done by contract.

In still another case measurements show that in trees up to 14 inches in diameter, 57 per cent of the merchantable contents of the trees cut was actually utilized, and that in the case of trees over 14 inches, 66 per cent of the merchantable contents of the trees cut was utilized. This cutting was done by a purchaser of stumpage in virgin timber in which the trees were comparatively large and the waste should have been small.

In another series of measurements on still another cutting in which the circumstances and locality were the same as for the data last given, 56.9 per cent of the material cut was saved. For another region the measurements (Blodgett rule) taken show that 84 and 86 per cent of trees cut under and above 14 inches, respectively, were actually utilized. A series of measurements where the cutting was done by owners of land for their own mills shows that with trees up to 14 inches in diameter, approximately 70 per cent of the material was utilized, and with trees over 14 inches 72 per cent was utilized. These data include only the waste in stumps and tops and not the valuable material used in road construction when other timber was available, partly merchantable trees which were not cut at all, and the loss occasioned by disregard of reproduction.

Measurements taken on 32 trees cut on the Fort Wingate Military Reservation showed that 23 per cent of the merchantable contents of the trees cut was wasted in tops and stumps.

In a national forest sale in southern Wyoming in a stand made up of Engelmann spruce and lodgepole pine, chiefly the latter, 58 per cent of the total cut was utilized as hewn railroad ties, 24 per cent as mining props, and 18 per cent as saw timber. In many of the old operations of this region ties were cut and the timber suitable for other materials, such as props and saw timber, was left in the woods. In many other operations materials other than ties and saw timber have not been utilized. It is obvious, therefore, that in such cases about 24 per cent of the merchantable material, on the basis of the sale above mentioned, was left in the woods.

The following extract from Forest Service Bulletin No. 69 gives an idea of the utilization of valuable species, such as the sugar pine. While utilization was close under the existing conditions, it is much more so at the present time because of still higher market prices.

> From a financial standpoint there is almost no waste in logging, though often the actual waste of timber is considerable. Stumps are cut 3 feet in height or even less, merchantable logs are seldom left in the woods, and the trees are cut fairly well into the tops. The size at the end of the last log varies a good deal with the character of the individual tree. In general, logs are cut to about 14 inches at the small end, though occasionally they may be cut as small as 10 inches.
>
> From what has been said it may be judged that the lumberman is beginning to realize the necessity of logging as closely as possible. How close he may log must depend on his particular operation and the attending conditions. Since these conditions vary greatly, it is natural that the economy of logging operations should also differ widely. Most of the large concerns are now hauling to their mills sugar-pine logs that have been lying on the ground thirty or forty years. The sapwood of these logs has, of course, rotted away, but the heartwood is usually as sound as on the day the trees were cut. One big lumber company is cutting its tops and limbs into firewood, which it handles at a small profit per cord. This it is enabled to do by the existence of a good market near at hand, with which it is connected by its own railroad.
>
> At least one company has reduced its loss in the fire-scarred butts of sugar pine to a minimum, for it cuts the butt log as though the fire scar did not exist, hauls it to the mill, and as far as possible, cuts it into full-length boards. What is left is then cut into "shorts."

The following extracts from an article in the Dixie Wood Worker of December, 1905, gives a lumberman's estimate of the loss in logging in the southern pine region:

CUT THE STUMPS LOWER.

> Most woods foremen allow the stumps to be cut too high. From 2½ to 3 feet is the average in the southern pine region. * * * Nevertheless, the southern pine woods foreman permits a large amount of timber to be ruined by allowing his saw crews to fell timber across stumps, or down timber, and to break off standing trees by the falling of others against them. The appearance of most cut-over pine land in the South shows how very great the damage is from this source. The ground is strewn with broken tree sections which have been butted out, and is dotted here and there with the splintered trunks of promising young trees deprived of their crowns. In heavy stands of southern pine as much as 400 feet per acre on an average is sometimes destroyed by the careless felling of timber. A zealous woods foreman would put an end to a

> large part of this careless waste by insisting that the sawyers use the greatest caution in felling timber. A certain amount of breakage is, of course, unavoidable, but most of it is due to sheer carelessness on the part of shiftless workmen. Such men often waste wantonly several times their wages in timber. Summary discharge of the conspicuously careless would have a good effect on the rest of the men. * * *
>
> A good woods foreman will impress on his saw crew the importance of so arranging their log lengths that a bad defect, such as a punk knot or rot hole, will come at the end of the log rather than in the middle of it. In many cases it would be best to butt out the bad place. If left in the middle of the log, however, it is impossible to trim the defective boards at the mill, and they must grade as No. 2 or No. 3 common.
>
> Another bad arrangement of log lengths is to run the end of an otherwise clear log just beyond a large knot or pitch pocket, making it necessary to trim away the defective end in order that the boards may grade as clear. The defective part might just as well have been put into the next log, which is knotty and will make only the lower grades.
>
> ### DECIDING ON WHAT LOGS TO CULL.
>
> The skill of the woods foreman is never tried more severely than when he decides what logs are not worth sending to the mill. Crooked, hollow, swell-butted, and doty logs, each is a problem in itself, and at best the judgment of the foreman is only guesswork. Close observation of what defective logs saw out in the mill will, however, enable him to guess more accurately from day to day. Lumber companies waste a great deal of money by sawing timber so small or defective as to be not worth taking; on the other hand, other lumber companies waste money by leaving in the woods timber which really would pay for the taking. I know of an instance where a lumber company operating in southern pine in one of the Gulf States made it a practice to leave in the woods all knotty, top logs below a certain diameter. The cut-over lands of this company are strewn with tops, many of which contained logs 10 to 18 feet long, more or less knotty. The company based its rule on the assumption that such logs would not saw out anything better than No. 2 commons; yet a study of the results from sawing this same class of material in a neighboring sawmill disclosed the fact that they yielded enough of No. 1 commons to afford a nice margin of profit.

The great item of waste in logging in the Northwest is breakage, and a little additional height in the stumps, which may seem unnecessary, really reduces, it is claimed, to a great extent the loss which might otherwise occur from this cause. In the larch operations of northern Montana, Idaho, and eastern Washington, lumbermen consider it necessary to cut off quite a large piece of the butt log of large trees in particular. This, in operations in the national forests where it is necessary to drive the logs which are utilized, amounts to as much as 5 or 10 per cent of the total cut of the species. In private operations, however, the loss from this practice alone is very much greater. The great percentage of loss in redwood operations is too well known to require comment. No accurate data, however, are available.

The utilization of saw timber throughout the hardwood region is, as a rule, very incomplete. In parts of the hardwood district in which coal and gas are available and cheap for fuel, all of the material suitable for cord wood must be left, in addition to the waste in the saw-timber product. In other parts of the hardwood region where coal and gas can not be obtained at low rates, the material which is not utilized for saw timber is disposed of as cord wood. Frequently, however, far too much material which is suitable for saw timber is worked into cord wood. The Doyle scale rule, which is almost universally used in the hardwood district, is perhaps responsible to some extent for the waste, on account of the very small value it allows for small logs.

Forest Service Bulletin No. 73 states that by a judicious selection of the proper lengths for cutting logs as much as 25 per cent may be saved in some cases. It is necessary for the woodsman to be able to judge accurately from the outside appearance of the log the kind of lumber which it will cut. The appropriate selection of log lengths throws serious defects into such parts of the log that the amount of waste is reduced to a minimum.

In the report on "Forest conditions in Kentucky," Messrs. Holmes and Bradfield, of the Forest Service, estimated that the waste in floating, weathering, and discoloring in driving logs amounts to at least 10 per cent, and if logs are stranded or in any other way delayed for two or more seasons in reaching the mill this loss amounts to 15 to 20 per cent.

Mr. Patterson, in a report on the cutting of a company in western Kentucky, states that stumps are cut from 22 to 30 inches in height, and that the average loss per tree at the stumpage rates paid in the year 1905 was 15 cents.

SHINGLES.

The great bulk of shingles which are made in the East are manufactured from material which would otherwise go to waste; that is, from slabs, short pieces, etc. In the West, however, particularly in the cedar district of Washington and in Oregon, operations in which cedar is the only product are common. Stumps are necessarily cut very high, since, on account of the grain, a good grade of shingles can not be made below the point at which the butt swell begins. These stumps, however, are not very much higher than stumps in a saw-timber operation. Cedar for shingles can not be utilized so far into the tops as saw-timber material on account of limbs and knots, but this waste is not so great as might at first appear, because of the very rapid taper of the average cedar tree. Operations confined to cedar for shingles alone usually result in considerable damage to the remaining timber which is not removed. Since many of the cedar-shingle operations of the present time include only dead timber, utilization in that respect may be classed as very complete. The fact that cedar is split into bolts before manufacture is responsible for quite a large percentage of waste.

PULP WOOD.

Considerable data have already been given regarding waste in operations in the Adirondacks and New England in pulp-wood operations. The great bulk of pulp wood is obtained from the spruce region of the Adirondacks and the Northeast, and, as a rule, utilization at the present time is wonderfully complete. As previously stated, tops are commonly taken to a diameter of 5, or even 4, inches, and stumps are cut low.

WOOD FOR DISTILLATION.

Utilization in the woods for materials to be used for distillation is probably as complete as for any other operation in the United States to-day.

HEWED CROSS-TIES.

The following extract from Forest Service Circular No. 118 gives an idea of the waste in tie making in eastern hard woods.

Tables 1 and 2 give a clear idea of the wastefulness of the present methods of tie production. Out of every 100 trees cut for ties over 63 are taken to a top diameter of from 10 to 13 inches instead of 9 or 9½ inches, the smallest diameter from which a 6 by 8 inch tie can be made. Out of 100 trees of 14 inches and over whose butt logs could be split, two-thirds remain entirely unsplit, and of the remainder only a small number are split into the number of ties justified by the size of the logs.

Table 1 brings out strikingly the wastefulness of the present manner of tie cutting. Where ties were being cut, 100 trees, embracing all diameters from 10 to 19 inches, were measured, the actual number of ties yielded by each ascertained, and the total cubic contents of each of the trees, as well as the contents of the portion used for ties, computed.

TABLE I.—*Waste in producing slab cross-ties.*[a]

Diameter of trees breast-high.	Volume of usable length of tree.	Volume of used length of tree.	Ties produced.	Waste of used length of tree.		Waste of usable length of tree.		Wood used for one tie based on used length of tree.	Wood used for one tie based on usable length of tree.
Inches.	*Cu. ft.*	*Cu. ft.*	*Number.*	*Cu. ft.*	*Per ct.*	*Cu. ft.*	*Per ct.*	*Cu. ft.*	*Cu. ft.*
10	14.3	6.1	1.3	2.6	43	10.8	76	4.7	11.0
11	18.5	9.5	1.7	5.0	53	14.0	76	5.6	10.9

17	54.5	35.7	4.2	24.5	69	43.3	79	8.5	13.0
18	65.5	43.1	4.7	30.6	71	53.0	81	9.2	13.9
19	76.5	51.3	5.2	37.4	73	62.6	82	9.9	14.7

[a] Assuming each tie to contain 2.67 cubic feet.

Thus from 43 to 73 per cent of the logs used for ties and from 75 to 82 per cent of the whole tree are entirely wasted. This waste is enormous, if we consider how much wood must be consumed to produce the 20,000,000 or more ties which are each year cut in the region. It amounts to about 221,000,000 cubic feet of wood, on the basis of the entire merchantable contents of the tree, or 140,000,000 cubic feet of logs, on the basis of the part actually cut. Of the total amount of timber cut for ties nearly three-fourths is wasted. That this waste can be much reduced is proved by tie cutting in Germany. There also the majority of ties are hewed, while the common tie is larger than our standard tie. It is 8.17 feet (2.5 meters) long, has 10.2 inches (26 cm.) face, is 6.29 inches (16 cm.) thick, and contains 3.5 cubic feet instead of our 2.67 cubic feet. Yet in Germany it takes only from 4.4 to 5 cubic feet of log to produce one tie, while in this country it takes on an average from 7.5 to 8 cubic feet of log to produce a smaller tie. In spite of very strict specifications, the waste of timber in hewing does not there exceed 30 or 40 per cent of the log, while in this country it reaches 73 per cent, to say nothing of the top, which remains entirely unused. The waste in hewing oak ties is greater than in hewing pine ties, since it takes about 11 cubic feet of hardwood timber to produce one tie, and only 9 cubic feet of pine wood. This is due not to any greater waste necessarily involved in hewing hardwood ties, but to the smaller taper and proportionately longer clear length of the pine as compared with oak.

With no inspection of the sizes and characters of the trees cut, the tie makers are guided in their choice of tie timber and the portion of each tree to be used for ties merely by their own convenience and by the ease with which the trees may be hewed into ties. By taking each tree to a top diameter of 9 inches outside the bark, cutting stumps not higher than 2 feet from the ground, and splitting into ties all logs large enough, an increase of from 67 to 185 per cent can be effected in the yield of individual trees above 15 inches in diameter.

This is shown in Table 2, which compares the average number of black-oak ties obtainable under the present practice and the number possible under more economical methods of tie cutting. The possible yield of ties per tree is based on the taper measurements of black oak.

TABLE II.—*Comparison of the average number of black oak ties per tree obtained under present practice, with the number possible under more economical methods of tie cutting.*

19	4.9	13.5	176
20	5.4	15.4	185

[a] Trees under 12 inches can not be used economically for ties.

Under more rigid supervision the present yield in ties per acre could in a great many cases be doubled and even trebled, if all trees large enough were made into ties. At present many trees are left uncut, not out of consideration for the future of the forest, but because they are too large, tough, or crooked to be easily hewed into ties, while the straightest and youngest trees are taken because they yield the greatest number of ties with the least effort. Table 3 gives the actual yield of 15 sample acres and an estimate of what could be obtained from them if all the trees of tie size were made into ties under present methods and under more economical methods.

TABLE III.—*Comparative yield of ties per acre under present sytsem and under more economical methods.*

Age of stand (years).	Type.	Actual yield of ties.	Yield by taking all trees of tie size by the present methods.	Possible yield of ties by taking and fully utilizing all trees of tie size.

65 to 70	do	42	105	112
68 to 73	Ridge	54	162	187

By taking all trees that can be made into ties, even as cutting is now practiced, the yield per acre would be increased by from 60 to 125 ties, and with the closest utilization of each tree an increase of 170 ties might be secured from each acre. In this way, to supply the required number of ties, the forest area now annually cut over for ties could be reduced nearly two-thirds and the revenue per acre increased.

The greatest economy would be effected in the utilization of the timber if all trees above 13 or 14 inches in diameter were sawed instead of hewed into ties. Where sawed ties are as readily accepted as hewed ones, and where logging is not difficult, sawing will usually prove cheaper and more profitable than hewing.

The following data from Forest Service Bulletin No. 64, published in 1905, give an idea of unnecessary waste in cutting ties in Texas:

WASTE IN HEWED TIES.

Since the tie inspectors do not object to, but even favor ties of greater dimensions than 6 inches by 8 inches, the tie maker never hews a large log to the minimum size. A hewn tie therefore contains as a rule more than the 32 board feet which are contained in a sawed tie of the specified dimensions. This waste of timber, though considerable, is less than that which goes into slabs and chips in hewing.

Table XXV is compiled from records made of the actual yield of 603 trees, and conveys an idea of the sum of these wastes. It shows that from 54 to 71 per cent of the timber cut for pole ties goes into slabs and excessive dimensions. If to this waste is added the timber lost in unreasonably high stumps, and the large tops left entirely unused, the proportion of the tree actually used in the shape of ties is exceedingly small. Thus, only from 26 to 30 per cent of the total volume of the tree is made remunerative, while the rest, 70 to 74 per cent, is either thrown away entirely or practically wasted in making needlessly large ties. These figures of course include some material that could not be used in any case, e. g., the tops above 9 inches. The statement is made in this way solely to show how small a proportion of the forest is utilized and to emphasize the importance of the economies that are recommended farther on.

TABLE XXV.—*Amount of timber wasted by making hewed pole ties.*

17	62.0	54.3	16.0	71	74

[a] Exclusive of branches.

The figures of the average number of ties actually yielded by trees of different diameters, Table XXIV, do not represent all that could be obtained from the same trees under a more careful and economical system of cutting. Since the tie makers are paid by the tie, their aim is to make as many as possible in the shortest time and in the easiest way. They commonly avoid all crooked and knotty trees, and fell only the tallest and straightest ones, those which will yield the greatest number of ties. Because the butt of the tree is tough and requires most ax work, the stumps are cut as a rule excessively high, seldom less than 2.5 feet in trees of small diameters, and often 3 feet to 4 feet in the larger trees. Many trees, after being felled, are also butted off 3 or 4 feet, because they are too large to be hewed easily. Another means of saving work is to saw the trees through about three-fourths of their thickness, and throw them by means of wedges driven into the kerf. In falling, the tree splits up for a considerable length and leaves a long slab attached to the stump which would otherwise have to be taken off the log by the ax. Old suppressed trees, which after being felled prove hard to hew, are frequently left to rot, or only a small part of what could be made into ties is used. Most of the trees felled for ties could be safely used to a diameter of 9 inches in the top, but the tie cutter, guessing at the size and unwilling to risk making a cull tie (one below the specified dimensions), for which he is not paid, remains on the safe side and seldom cuts beyond 10 inches. Often a large part of a tree with a knot or crook, or slightly buried in the sand so that it is difficult to saw into the proper lengths, is left unused.

POSSIBLE SAVINGS IN TIE MAKING.

Many of the wastes that have been just described are easy to reduce or to eliminate entirely. By merely cutting the stumps about 2 feet high or less and utilizing all the tie timber in each tree the average number of ties to the tree could be perceptibly raised.

Table XXVI shows clearly how great a saving may be effected by cutting all stumps at 2 feet above the ground and utilizing the stem to 9 inches in diameter outside the bark at the top. The figures are based upon taper measurements of 603 trees.

TABLE XXVI.—*Average number of hewed ties now obtained from loblolly pine and number that can be cut.*

Diameter breast high.	Number obtained.	Number which can be obtained.	Percentage of increase.
Inches.			
11	2.4	2.5	4
12	3.1	3.5	13
13	3.9	4.5	15
14	4.8	5.5	15
15	5.2	6.0	15
16	5.7	6.5	14
17	6.0	7.0	17

The increased number of ties that it is possible to obtain is somewhat variable, because lengths of 8 feet must always be cut, yet the gain is very real, and amounts to considerable when applied to even 1 acre of forest. Taking the figures of Table I as an example, it requires but a simple calculation to show that the 93 trees between 11 and 17 inches in diameter produced by 1 acre of forest from 35 to 40 years old may yield 45 more ties than they do ordinarily. If this be applied to a piece of land yielding 40,000 ties, the increase will amount to at least 5,000 ties, worth, at the present price of 24 cents a tie, $1,200.

HEWED VERSUS SAWED TIES.

The hewing of ties, however, no matter how complete the utilization of the tree may be, is a most wasteful process, whose extent will be best understood by comparing the volume of average hewed ties with the product of logs of the same dimensions sawed into ties and lumber. By means of a series of diagrams the amount of lumber and ties which can be obtained from logs of various sizes by sawing has been ascertained. A large part of the log, which in hewing is entirely wasted in the form of chips and excessive dimensions, is thus shown to be available for useful material—boards and planks.

It is impracticable to make a direct comparison between the tie and the lumber yield of trees of various sizes, because the hewers might be more saving, and because the lengths obtainable are not always multiples of the tie length, 8 feet, but such a comparison can be made on the basis of logs 16 feet long, which will produce two ties, or lumber of standard length. This is done in Table XXVII, and the possibility of sawing from 23 per cent of the hewed tie volume, in 10-inch logs, to 191 per cent in 15-inch logs is clearly shown. The saving here indicated may rarely be reached in practice, since the logs are not apt to be perfectly cylindrical nor straight, as the diagrams from which the table was made assume them to be, yet after making every reasonable allowance for such irregularities, the waste in hewed ties is striking.

TABLE XXVII.—*Gain in lumber effected by sawing instead of hewing ties.*

	In hewed ties.	In sawed ties and lumber.			
		Ties.	Lumber.	Total.	
Inches.	*Board feet.*	*Board feet.*	*Board feet.*	*Board feet.*	*Per cent.*
10	64	64	14.8	78.8	23
11	64	64	27.0	91.0	42
12	64	64	52.4	116.4	82
13	64	64	70.8	134.8	112
14	64	64	97.2	161.2	152
15	64	128	57.6	185.6	191

TREE SIZES MOST PROFITABLE FOR TIES.

There is a still more important reason why ties should be sawed instead of hewed than the saving of lumber, namely, that the latter method demands those trees which are in their best period of growth. As has been shown, the tie cutters prefer trees 12, 13, 14, and 15 inches in diameter, or between 30 and 50 years of age, when they are still growing rapidly in diameter.

Table XXVIII shows that the rate of diameter increase in trees of the sizes used for hewed ties, though steadily falling, is maintained at more than one-quarter of an inch a year until the age of 50 years is passed.

TABLE XXVIII.—*Increase in diameter of loblolly pine grown in mixture with hard woods on well-drained, fertile soil.*

Age.	Diameter breast high.	Annual increase in diameter.	Age.	Diameter breast high.	Annual increase in diameter.
Years.	*Inches.*	*Inch.*	*Years.*	*Inches.*	*Inch.*
10	2.1	0.40	50	15	0.22
20	6.1	.34	60	17.2	.21
30	9.5	.29	70	19.3	....
40	12.4	.26			

But the loss that is entailed by cutting immature trees is made much more apparent when the increasing money value of the trees is considered. This is shown in Table XXIX.

TABLE XXIX.—*Rate of increase in stumpage value of loblolly pine trees suitable for ties, grown in mixture with hard woods on well-drained, fertile soil.*

Diameter breast-high.	Value of tree at 3 cents a tie.	Annual rate of increase.	Diameter breast-high.	Value of tree at 3 cents a tie.	Annual rate of increase.
Inches.	*Cents.*	*Per cent.*	*Inches.*	*Cents.*	*Per cent.*
11	7.5	8	15	16.5	2
12	9.9	8	16	18.0	....
13	12.3	5	17	18.0	....
14	15.0	3			

These two tables show that the rate of increase in diameter and in value for hewed ties is greater in the smaller trees than in those from 14 to 16 inches in diameter. In other words, the money capital represented by the trees of 11 and 12 inches in diameter increases at a rate equal to an interest of 8 per cent per annum, while the capital represented by trees of from 13 to 16 inches in diameter bears interest at the annual rate of only 2.5 per cent. If the owner of the land were to cut down all the loblolly pine trees between 11 and 13 inches in diameter and place the money received for them in some safe enterprise, he would scarcely receive such a high rate of interest as he does from the growing trees. If it is necessary that the trees should be cut for hewed pole ties, only those 15, 16, and 17 inches in diameter should be used, as their rate of increase in value is smaller than that of trees 11, 12, and 13 inches in diameter. In this way the capital is allowed to work at a higher rate of interest.

Further, the forest is not threatened with entire destruction. In a forest from which regular and sustained yields are expected, trees of all ages must be present and the young ones must preponderate over the old ones, just as in a self-perpetuating community the number of children must be greater than the number of adults. By cutting out the young trees and leaving the old ones, as is now the common rule, the very existence of the forest is attacked. Since hewing the trees into ties instead of sawing them entails more labor and greater waste, it is clear that to get the greatest income from the forest the practice of hewing must give place to sawing.

There is still another consideration. Trees cut for the mill are usually more fully utilized than those cut for hewed ties. Table XXX, based on actual scaling in the woods of trees cut for hewed poles and of the trees of the same diameter cut for the mill, reveals a greater utilization of the trees in the latter case than in the former one, the increase amounting to from 20 to 45 per cent.

TABLE XXX.—*Comparison of the product of loblolly pine grown in mixture with hard woods on well-drained, fertile soil when hewed into ties and when cut into saw logs.*

Diameter breast-high.	Trees cut for pole ties.		Trees cut for saw logs.		
	Number.	Yield per tree.	Number.	Yield per tree.	Excess in saw logs.
Inches.		*Board feet.*[a]		*Board feet.*[a]	*Per cent.*
11	31	35	9	45	29
12	135	53	32	63	20
13	178	70	50	87	24
14	161	90	64	114	27
15	79	108	78	144	22
16	17	125	79	175	40
17	1	145	79	210	45

[a] Doyle-Scribner log rule.

From the point of view of the forest owner, however, this difference is not apparent. At the present stumpage price for lumber and ties he is willing, in the majority of cases, to have his young loblolly pines cut for ties instead of lumber, because the tie timber brings him a slightly higher price per tree, as can be seen from Table XXXI.

TABLE XXXI.—*Comparative values of loblolly pine from all situations, if sold for pole ties or for lumber.*

Diameter breast-high.	Volume of tree.		Value of tree.	
	Lumber.[a]	Hewed ties.	At 75 cents per M. board feet.	At 3 cents per tie.
Inches.	*Board ft.*	*Number.*	*Cents.*	*Cents.*
11	43	2.4	3.2	7.2
12	64	3.1	4.8	9.3
13	86	3.9	6.5	11.7
14	110	4.8	8.3	14.4
15	138	5.2	10.4	15.6
16	171	5.7	12.8	17.1
17	207	6.0	15.5	18.0

[a] Doyle-Scribner log rule.

The smaller value of the tree when cut for lumber is due mainly to the log scales now in vogue, which give an exceedingly low scale to small logs as compared with their actual contents. The extent of this difference is shown on Table 32, though the argument for sawing must rest upon other considerations, since it will be hard to alter the established practice in scaling.

TABLE XXXII.—*Comparative log and tie scales of loblolly pine, grown in mixture with hard woods, actually cut for ties.*

Diameter breast-high.	Scale of the unhewed logs.	Ties cut from tree.	Scale of the hewed ties at 32 feet each.	Excess of tie over log scale.	Diameter, breast-high.	Scale of the unhewed logs.	Ties cut from tree.	Scale of the hewed ties at 32 feet each.	Excess of tie over log scale.
Inches.	*Board ft.*[a]	*Number.*	*Board ft.*	*Per cent.*	*Inches.*	*Board ft.*	*Number.*	*Board ft.*	*Per cent.*
11	35	2.5	80.0	129	15	108	5.5	176.0	63
12	53	3.3	105.6	99	16	125	6.0	192.0	54
13	70	4.1	131.2	87	17	145	6.0	192.0	32
14	90	5.0	160.0	77					

[a] Doyle-Scribner log rule.

In this connection it is proper to consider why trees are hewn at all. One would naturally expect that the persistent demand for hewed pole ties, the production of which is coupled with such a waste of timber and the most extravagant use of the forest, must be based on very good reasons, and that the railroads are paying a higher price than for sawed ties, as is the case with those made of longleaf pine and other woods. As a matter of fact, however, hewed and sawed ties of loblolly pine command exactly the same price in eastern Texas. The apparent reason for the preference is that hewed ties are thought to last longer than sawed ones, because the smooth surface made by the ax is less retentive of the water that promotes decay than is the sawed wood. There may be some truth in this when untreated ties are considered, but since all the loblolly-pine ties now used are treated before they are laid in the track the objection does not hold. According to Doctor von Schrenk,[a] sawed ties when properly treated, last as long as hewed ones, and there is no good reason why they should not be used. The farmers of Texas probably will continue to furnish hewed ties so long as they are demanded, in spite of the drain on their forests, but the railroads can easily curtail the waste by encouraging the production of sawed ties. The railroads are heavy consumers of timber in many forms. Besides ties, they require every year enormous quantities of bridge timber, telegraph poles, and lumber for cars and houses. The present wasteful use of young timber for ties, which could readily be avoided, will lead to a rapid exhaustion of the timber supply in general, which can not remain without influence upon the lumber market.

In some instances the cutting of young timber for hewed ties may be justified. Where the stand is very dense the removal of the trees which lagged behind in the competition for light and room would prove beneficial to the growth of those remaining. Since from the several thousand young seedlings which usually start on an acre only from 140 to 160 trees reach maturity, timely thinning would perceptibly increase the yield per acre by furnishing useful material which would otherwise decay in the woods and add to the danger from insects and fires. If, however, the cutting of pole ties were limited to trees removed in thinnings, a qualified person would be required to mark every tree which should be cut, and that could be profitably done only by owners of large forest tracts.

---

[a] "The Decay of Timber and Methods of Preventing it," by Herman von Schrenk, Bulletin No. 14, Bureau of Plant Industry, U. S. Department of Agriculture, p. 22.

The following table, taken from Bureau of Forestry Bulletin No. 53, Chestnut in Southern Maryland, shows the total length of material wasted in tops of trees cut for hewn ties.

Diameter breast-high.	Volume.	Length wasted.	Diameter breast-high.	Volume.	Length wasted.
Inches.	*Ties.*	*Feet.*	*Inches.*	*Ties.*	*Feet.*
10	1	51	16	5	41
11	2	48	17	5	43
12	3	44	18	5	45
13	3	49	19	5	47
14	4	43	20	5	49
15	4	46			

The waste of timber which attends the cutting, as shown in the table, is very great, but the demand for chestnut tops for other purposes is comparatively small.

STAVES.

In a report on the tight-cooperage industry Mr. H. M. Hale, of the Forest Service, states that the greatest waste in tight cooperage occurs in the manufacture of split staves. He further states that by far the greater number of export staves at the present time are split. In 1897, 51,120,171 staves were exported. The manufacture of staves by splitting is particularly wasteful, since only butt logs and particularly straight-grained sticks—or, in other words, the highest class of timber—can be used.

The following table of measurements taken in Kentucky shows the diameter breast-high and the top diameter to which white-oak trees were used for split staves:

Diameter breast-high.	Top diameter.	Diameter breast-high.	Top diameter.
Inches.	*Inches.*	*Inches.*	*Inches.*
16	15.1	27	20.7
17	15.5	28	21.4
18	15.9	29	22.0
19	16.3	30	22.7
20	16.7	31	23.3
21	17.2	32	24.0
22	17.7	33	24.7
23	18.3	34	25.3
24	18.9	35	26.0
25	19.5	36	26.7
26	20.1		

It will be seen from this table that the top diameter varies from 15.1 inches in a 16-inch tree to 26.7 inches in a 36-inch tree. It is obvious that the amount of waste, especially in large trees, is very great.

The following facts are taken from a report on Woods for Slack Cooperage and Their Economic Utilization, by J. J. Levison, of the Forest Service. In the manufacture of slack cooperage under present methods it is absolutely necessary to use green timber. Even after green timber is cut it is frequently allowed to lie in the woods so long that it becomes too dry or too checked for cooperage purposes. As in the case of saw logs, heading blocks are frequently cut too long. Mr. Levison states that blocks are frequently cut to the length of 21 inches, when only 17½ or 15-inch heading will be cut from them. Logs intended for staves are cut in the woods to lengths which are multiples of 32 inches, because of poor judgment in the workman or wood superintendent, and it is often found necessary to utilize at the mill for heading, material which was cut in the woods for staves. In logs which were cut for 6-stave lengths the waste, if it is found necessary to utilize the log for heading, is 3 inches to the log. If, on the other hand, the log was cut for 5-stave lengths, the waste, if it is necessary to utilize this for heading, is 13 inches. Not infrequently, through carelessness of workmen, logs are cut too short in the woods and the last block must be thrown out at the mill. As in other industries, it is necessary to combine several industries in order to secure complete utilization. For instance, in the manufacture of slack cooperage materials (heading, stave, and hoop mills) logs that will not make good hoops will freguently make good staves, and logs which are not suitable for staves will often make very good heading.

The following is an extract from The National Cooper Journal, of November, 1905, on the question of waste in the cooperage industry:

> Here in the veneer mill the man at the drag saw must cut his blocks longer than the veneer to be made from them, so that there may be plenty of room to use score knives and true up the end. Sometimes we work this very closely, and get it down to 2 or 3 inches, and then again there are times when there are from 2 to 4 inches on each end, making a total waste of 6 inches. After marking off the log, then there is a chance that the drag sawyer may have to cut off one end anywhere from 3 inches to a foot of log, and that goes into the waste pile.

POLES.

Operations which have in view only the exploitation of poles, as previously indicated, result in considerable damage to the remaining timber in the stand. In the West and Northwest very frequently it is thought to be necessary to cut very high stumps in order to remove large butts which would make the pole difficult to handle. The actual waste from the practice of long butting alone probably amounts to an average of 5 per cent or more of the material actually obtained. Another cause of waste is the necessity in many cases for cutting to specification.

VENEER STOCK.

The waste in cutting material for veneer stock is very similar to that in hard-wood saw-timber operations in the East. Obviously, however, only clear material can be used to good advantage, and specifications usually provide for diameters larger than 16 inches. Unless knotty logs and those smaller than 16 inches can be used for saw timber and other purposes, and very frequently this is not the case, such material is a total waste.

MINE TIMBERS.

The following extract from Circular No. 118 contains an estimate of the amount of waste in cutting mine timber in the southern Appalachians:

> In logging for mining timbers under present methods fully 40 per cent of the timber handled is wasted. The chief items of waste are high stumps, tops, partially used bolts, and even whole trees, which are felled and rejected because slightly twisted in grain. Of the different timbers used by the mines, the greatest demand upon the forest is for props, which are 3 or 4 inches square by from 4 to 9 feet in length, and for tram ties. Under such conditions clean logging and fullest utilization of the tops to a diameter of 4 inches should present no difficulty, if proper supervision is given to logging operations. To secure close utilization of timber it would be best to saw into the required sizes the rougher material from the tops, as well as the entire stems of those species which are difficult to split, instead of following the present practice of splitting the timber into props and rejecting all logs that will not split readily. If mining timber is cut into bolts of the required lengths in the woods, it can be sawed at the mines to the required sizes at a great saving over the present wasteful methods of manufacture by splitting.

CORD WOOD.

The great bulk of cord wood which is cut in the East at the present time is used for fuel, and a very large percentage of the total amount cut is taken from farmers' wood lots. It is almost the universal practice to cut the best trees for this purpose, since they can be cut and split much more easily than the poorer trees and the poorer species. When it is considered that saw timber is now selling for $5 or more per thousand feet b. m., and soft coal can be produced for from $3 to $5 a ton, the economic loss through the utilization of hard-wood material for cord wood, when it is suitable for saw timber, is very apparent.

A great amount of cord wood is wasted each year by failure on the part of lumber companies to work up cord wood even when there are good markets.

LUMBERMEN'S ESTIMATES OF WASTE.

While few lumbermen have made an effort to obtain exact data on unnecessary loss in logging operations, estimates by lumbermen and by secretaries of lumber associations are of decided interest. In order to obtain such estimates the following questions were sent to the secretaries of representative logging associations throughout the United States:

1. What is the percentage of loss in the average logging operation, or, if possible, in specific cases, through bad management, not considering the specific kinds of loss referred to in the following questions?
2. What is the percentage of loss through leaving inferior species in the woods, failure to cut trees which are partly merchantable, and leaving comparatively inaccessible bodies of timber?
3. What is the percentage of loss by leaving logs in the woods, lodged trees, the use of valuable material for roads or other construction purposes, unnecessarily high stumps, merchantable material left in tops, unnecessary lengths left for trimming, nonutilization of short-log lengths, and breakage in falling?
4. What is the indirect loss through fire and windfall which follows logging operations?

The following tabulation shows estimates submitted:

	Question—				
	1.	2.	3.	4.	
				Fire.	Windfall.

LOSS FOR THE UNITED STATES IN 1907.

The following table attempts an application of the data on waste for various classes of material to the cut for the year ending June 30, 1907. It must be borne in mind that the percentage used can not be exact, and accordingly has been placed extremely low in order to be conservative. Logging methods, since much of the data here given were collected, have become much less wasteful, and the percentages given in the data have accordingly been considerably reduced:

Material.	Cut in year ending December 31, 1907.	Equivalent quantity.	Percentage of product unnecessarily wasted.	Waste.
Timber:		*Cubic ft.*		*Cubic ft.*
Soft woods ... feet	31,001,225,000	2,584,000,000	12½	323,000,000
Hard woods ... do	9,254,929,000	771,000,000	15	116,000,000
Shingles ... number	11,824,475,000	106,000,000	5	5,000,000
Pulp wood ... cords	3,000,000	270,000,000	7½	20,000,000
Wood distillation ... do	1,280,000	115,000,000	5	6,000,000
Hewed cross-ties ... number	118,383,000	414,000,000	25	103,000,000
Heading:				
Tight ... sets	27,693,000	9,000,000	15	1,000,000
Slack ... do	106,074,000	18,000,000	15	3,000,000
Staves:				
Tight ... number	385,232,000	32,000,000	15	5,000,000
Slack ... do	1,175,977,000	29,000,000	10	3,000,000
Poles ... do	3,500,000	35,000,000	12½	4,000,000
Veneer ... feet	348,000,000	29,000,000	25	7,000,000
Mine timber ... cubic feet	165,000,000	165,000,000	12½	21,000,000
Cord wood ... cords	100,000,000	9,000,000,000	10	900,000,000
Total		13,577,000,000		1,517,000,000

HOW FAR CAN THESE FORMS OF WASTE BE REDUCED THROUGH CONSERVATIVE LOGGING?

UTILIZATION ON NATIONAL FORESTS.

The methods followed in handling the sale and cutting of timber upon the national forests, in so far as they concern utilization and the protection of young trees and reproduction, are of decided interest, and result in most cases in a reduction to a minimum amount of the unnecessary waste.

The boundaries of sales exceeding $100 in amount in nearly all cases follow natural features, such as streams and ridges, rather than the lines of legal subdivisions. All sale areas are, therefore, natural logging units, and this cheapens exploitation, and provides for the cutting of the comparatively inaccessible as well as of the accessible timber.

All sales include the dead timber upon a tract as well as the living. All species, even though comparatively inferior and difficult to market, are included in the sale.

The clauses of a national forest timber-sale contract which relate to utilization and the protection of the valuable species are taken up in detail.

Clauses provide for the marking by forest officers of all live timber that will be cut, and for a penalty of double stumpage rates for all unmarked living trees which are cut and all marked trees which are left. This enables forest officers to control absolutely the cutting of trees which, for the good of the forest, it is desired to remove, and retain those which, for the protection of the forest and the provision for a second cut, it is desirable to retain.

A clause names approximate minimum diameter limits to which trees will be marked, and makes provision for the variations of these limits for the good of the forest. In order that purchasers may know the plan to be followed, sample areas are marked upon application in advance of sale. The minimum approximate limits are varied with the species to leave more and larger trees of the desirable species, in order to perpetuate them against those trees whose proportions in the stand should gradually be reduced.

Other clauses provide for payment for merchantable timber used in construction work, in order to encourage the use of inferior trees and of unmerchantable dead timber wherever feasible; for the use of saws rather than axes in order to reduce the percentage of unnecessary waste; and for the closest possible utilization in the stumps and tops. These clauses are still further strengthened by a provision for a double stumpage charge for material wasted.

Another clause binds purchasers to the protection of young trees and those which are to be left, and provides penalties for careless work.

Provision is also made for brush disposal in such a manner as to reduce the fire menace to a minimum, or make the best provision for reproduction; and for a fire-fighting force to be at the call of the local officers of the Service.

Still other clauses provide for an overrun in logs, and a penalty charge if the overrun is exceeded; and require the purchaser to pay for material suitable for saw timber at saw-timber rates, thus guarding against the use of saw-timber material for cordwood.

All national forest timber-sale contracts require the utilization of all possible material under existing conditions.

One sale in western Montana includes saw timber, mining stulls, converter poles, lagging poles, and cord wood, and utilizes all merchantable material which the purchaser is allowed to remove, to a diameter of 3 inches.

That lumbermen are purchasing timber under these restrictions and are making a profit from their operations is conclusive proof that much of the waste in the ordinary cutting is absolutely unnecessary.

ILLUSTRATIONS FROM PRIVATE OPERATIONS.

The following extract from Forest Service Circular 131, by Mr. Austin Cary, shows what may be done by complete inspection to reduce the unnecessary waste in logging. The plan would apply equally to practically all kinds of logging operations on private lands:

> Windfalls and dead standing timber are common in the virgin spruce woods of New England, and come under this head (cases in which the required utilization can not be definitely defined). The trees are often defective, and are more expensive to haul than live timber, but with present lumber prices it means a distinct loss to the owner if such material is left on the ground. At the expense of a good deal of labor thrown away in testing, this class of timber was carefully picked up. In just such a case as this, where expense has constantly to be balanced with availability at the mill, was shown the utility of inspection. A thoroughly posted man was on the ground every two or three weeks during the logging season to explain requirements, settle doubtful points, and keep things up to tone. That this paid for itself was perfectly evident. If ordinary logging was costing $4 per thousand, it might cost half as much more to pick up the windfalls and dry timber, a fact which told in the average cost of the whole cut. And yet at that figure there was a margin on even low-grade lumber, while much of the material gained was as good as the best. As a matter of fact, the rate of profit on all this class of stuff was larger than that on the main ouput of many other industries, while the amount saved the company would have made a handsome business for many lumbermen.

Below is a copy of the inspector's report as used by the Berlin Mills Company from Forest Conditions in Maine in 1902:

Camp of------------------------------, township------------------------------

> This inspection report represents the most effective control which we have been able to exert on our logging bosses and contractors. The work of each camp is inspected once every three weeks, and the past winter all the roads cut by the crew in the interval were gone over by the inspector, looking carefully after each item of waste. By this means foremen have been stimulated to look more carefully after this work than ever before, and in respect to

economy at least, loss of stuff left in the woods, greatly improved results have been obtained.

* * * * * * *

Below is a summary of the waste discovered in the work of six camps which were under the inspection of the writer during the winter of 1901-2. In explanation it will be necessary to append the following: By poles are meant small sticks scaling 20 feet or less, b. m., and down to about 7 inches on the stump. Under down and uprooting trees is put everything of that description seen on the ground cut over. In some cases these trees lay so hard no man would go after them; in others they may have been easy to get. The two classes can not be distinguished here. The waste in stumps and tops is a matter of judgment in which the inspector might be a good deal off, as no very extended studies or computations were made in the matter. Where a man kept his work as close to orders as could with reason be expected, no charge was made against him. Stumps were to be cut down to the swell of the roots and shoveled out if the snow was deep enough to require it. It was meant that no tops should be cut larger than 6 inches, and by far the most were much less.

This table shows the merchantable timber left to waste by six Berlin Mills Company's camps under close inspection:

Camp.	Total lumber cut.	Waste in stumps and tops.	Logs and trees cut and left.	Poles.	Lodged trees.	Standing dry timber.	Down and uprooting trees.	Sure to blow down.	Total.	Percentage of cut.
	Feet.	*Feet.*	*Feet.*	*Feet.*	*Feet.*	*Feet.*	*Feet.*	*Feet.*	*Feet.*	*Feet.*

Total waste in 15,600,000 feet cut, 250,000, or 1.47 per cent. That can and will be improved upon, but still there are logging concerns in the State which waste twenty times as much in proportion.

The term "sure to blow down," as applied to stuff left by the loggers, explains itself. In most of the operations it was not meant to strip the land, but to leave the smaller timber to grow, where it could be safely done. Whether it will be safe is, of course, a matter of judgment. In inspecting I meant to be conservative, noting only what any experienced man, if he gave his mind to it, would feel sure was doomed to fall. I expect there will be more loss by wind in the future than is here included. Of course, it is understood that I do not claim to have seen all the waste that occurred. Some of it was covered up by brush and tops so that no man could get it all.

The following data show the comparative amount of waste in cutting stumps in two logging operations in the Adirondacks in which conditions were very nearly the same, and show very conclusively that under a system of inspection the waste in logging can be reduced. The data are taken from the preliminary working plan for Adirondacks lands belonging to the Hon. William C. Whitney, by H. S. Graves, 1899:

Average height of stumps cut at Santa Clara in 1898, and at Nehasane, N. Y., in 1897.

COMBINATIONS OF WOOD-USING PLANTS.

One of the most promising methods of securing complete utilization is through a proper combination of different kinds of wood-using plants. The national forest sale previously mentioned serves as an excellent illustration of such a combination. Sticks not less than 6 inches in diameter at the small end and not less than 12 feet in length, which are sound enough for mining timber or lumber, are cut into mining stulls or are used for saw timber. Converter poles are from 3 to 5 inches in diameter, and at least 20 feet long; logging poles are from 2 to 4 inches in diameter, and 12 or 16 feet long. All material, dead and living, to 3 inches in diameter, not suitable for the purposes mentioned, is utilized for cord wood.

A combination of sawmill and box factory provides for a most complete utilization, since top logs to a small diameter and exceedingly short logs, if transportation facilities are such that they can be brought to the mill, can be used profitably, and grades unsuitable for lumber make excellent box boards.

Sawmills and pulp mills are frequently combined to good advantage in the North and Northeast. The sawmill uses the large logs and the pulp mill the small logs and the slabs from the sawmill. Very frequently, where market conditions and transportation facilities warrant, it is possible to utilize material which is not suitable for saw timber, mining timber, etc., for cord wood.

The mixed hardwood forests of the East are composed of so many species especially adapted to different uses that complete utilization may be secured best by the operation of several plants. If combinations could be made of sawmill, cooperage, box, veneering, and turning plants, and waste of various forms could be used as cord wood, unnecessary waste in the hardwood region could largely be disposed of. Obviously, complete combinations of this kind are not everywhere feasible, but partial combinations would greatly improve present conditions.

The most powerful factor in securing complete utilization will be higher prices for the manufactured product. While the value and importance of various economies will be recognized by lumbermen, not until the scarcity of timber reflected in high prices makes it absolutely necessary for every concern which operates to utilize completely all merchantable material, will lumbermen practice strict economy of the forest resources on their timber lands. The statement is proved by conditions in European countries to-day. Utilization is complete in those countries where prices are high. Where prices are low, for instance in northern Norway, utilization is not more complete than in the United States.

The quotation from Forest Service Circular No. 131, shows the profit in one case from the utilization of inferior materials and close cutting in tops and stumps; and in other cases where only utilization and not the perpetuation of the forest is being considered there is no excuse, when the visible supply and demand in the United States is considered, for failure on the part of an operator to remove all material which can be disposed of at a profit.

In an article in the American Lumberman on "Waste and economy in handling North Carolina pine," Mr. George W. Roper states that factories are not allowed to ship as merchantable lumber in the rough any pieces shorter than 10 feet, and further states that the pieces of this length are limited to a certain percentage. Mr. Roper states that mills should sell No. 1 and No. 2 strips to a minimum length of 4 feet, and that pieces of both even and odd lengths, that is, 4, 5, 6, 7, and 8 feet, etc., should be placed on the market.

When the markets become such that short and odd lengths are salable and sawmill machinery is so adjusted as to allow the sawing of short logs, it is bound to result in much less waste in the woods.

Though apparently insignificant, the scale rule is responsible for much waste. In some cases a short log with a large diameter actually scales more than if the same log had been cut longer, but with a smaller top diameter, although the latter actually contains more lumber. So long as this condition lasts, it will be exceedingly difficult to require contract loggers, for instance, to log without waste.

PROTECTION OF REPRODUCTION.

Not until lumbermen believe that provision should be made for a second cut, and that forestry can be practiced on private lands at a profit, will the protection of reproduction in the logging operation itself and through the proper disposal of slash be seriously considered. The most reliable estimate which it is possible to obtain at the present time shows that the available supply of timber at the present rate of cutting will be practically exhausted in from twenty to thirty years. If lumbermen can be shown that by modifying present methods of cutting it is possible to provide for a second and clean cut within some such reasonable time as thirty years, not only will the economic gain to the country be incalculable, but what concerns the lumberman more, the vital and financial returns from the first cutting will not be greatly lessened because of more complete utilization, and at the same time provision will be made for large future returns. The cost of such management will be the possible initial increased cost of logging, and possibly reduction in present returns, the cost of technical management, and finally the cost of patrol and taxes. Taxes on cut-over lands, while probably excessive in most States at present, will without doubt be reduced to a just basis when the States fully understand the necessity of providing by judicious taxation for a future timber supply.

SUMMARY.

Data collected by men who are thoroughly familiar with market conditions and the possibilities in the utilization of timber show that at the present time in the United States there is much unnecessary waste in logging. This fact is also acknowledged by lumbermen. This unnecessary waste occurs because of conditions, or prejudice, or various kinds of bad management resulting in—

Poorly conceived and poorly executed logging plans.

Failure to remove from the woods merchantable material which is actually cut.

Failure to cut and remove inferior trees, partly defective trees, and inferior species which are merchantable.

Failure to remove small bodies of timber in comparatively inaccessible places on which the profit is low.

The removal of only one class of material from the forest when others are present and merchantable.

Failure to utilize merchantable dead timber.

When inferior trees and inferior species are available, the use for construction work of valuable species and valuable trees which can not be otherwise utilized at a later time.

Failure to use materials for the purposes to which they are best suited.

The cutting of trees for tan bark only, and waste of the logs.

The cutting of unnecessarily high stumps.

Failure to utilize all of the merchantable material in tops suitable for saw timber or cord wood or other use.

Failure in requiring the proper variation in log lengths.

The nonuse of odd and short log lengths.

Unnecessarily long trimming lengths.

Unnecessary breakage in felling and transportation.

Too great loss in driving; and

Careless use of logging machinery such as donkey engines.

In addition, through economic conditions such as taxes, low prices for manufactured products, ignorance and disregard of the value of young trees and reproduction, and the necessity of providing for future crops, the possibilities of future timber supplies have been greatly reduced, and the time for producing such supplies greatly extended through unnecessary damage to reproduction and young trees in logging operations, and the fires which follow logging operations in many cases because of failure to dispose properly of the slash resulting from the cutting.

Experience has shown that unnecessary logging waste on private lands may be reduced to less than 1.5 per cent by a proper form of inspection which, in modified forms, is fully applicable to all cutting on private lands.

Unnecessary waste in national forest cuttings through carefully prepared contracts and frequent inspection is not greater than 1.5 per cent on the average and in many sales the amount is negligible.

Suitable combinations of different kinds of wood-using plants can bring about a great reduction in unnecessary logging waste.

Increasing market prices without other influence will gradually bring about complete financial utilization, since lumbermen who log carelessly will not in the long run be able to compete successfully with lumbermen who utilize as fully as conditions will allow the products of the forest. This condition may, however, be greatly hastened by the means suggested.

The proper protection of the reproduction and of young trees in logging operations and the disposal of slash in such a manner as to reduce the fire menace in cut-over areas to a minimum will not be considered by lumbermen until the feasibility of conservative forest management has been demonstrated to them.

WASTE IN MILLING.

By Louis Margolin,
United States Forest Service.

SUMMARY.

WASTE IN MILLING.

In converting logs to lumber there is entailed a heavy waste. This waste may be necessary or unnecessary, and it may entail a total loss or only a relative loss.

Under present methods of manufacture the principal sources of waste are as follows:

1. Loss of bark; 10 to 20 per cent of the total volume of the log, with an approximate average loss of over 13 per cent. (See Table 3.)
2. Loss due to kerf; 15.5 per cent of the volume of the peeled log, or 13.5 per cent of the total volume of the log.
3. Loss due to edging and trimming; 10 per cent of the volume of the peeled log, or 8.7 per cent of the total volume. (See Table 2.)
4. Loss due to slabs; 10 per cent of the peeled volume, or 8.7 per cent of the total volume of the log. (See Table 2.)
5. Loss due to careless manufacture and accidents (not included in the above); 4 per cent of the peeled volume, or 3.5 per cent of the total volume of the log.
6. Loss due to standardizing lengths and widths of boards; 2 per cent of peeled volume, or 1.7 per cent of total volume.

The total loss from all sources is 49.1 per cent of the total volume of the log, and each cubic foot of log with bark yields, therefore, on an average 6.1 board feet of lumber.[a]

To manufacture the 40,250,000,000 feet of lumber produced in 1907 required 6,600,000,000 cubic feet of wood.

A portion of the waste is necessary and can not be avoided, but a large percentage can be saved in the following ways:

1. By the general adoption of thin saws—band saws and resaws.

---

[a] It may be of interest to compare this figure with the two standard log rules—the Doyle and the Scribner.

The average size of log cut in the United States is probably about 18 inches in diameter at the small end. Allowing a taper of 1 inch to 8 feet, the total volume of a log 16 feet long and 18 inches in diameter, peeled, is 31.5 cubic feet. The total volume of such a log, including the bark, is 36.21 cubic feet.

A log 16 feet long and 18 inches in diameter scales, according to the Doyle rule, 196 board feet, or 5.4 board feet per cubic foot of unpeeled log. The same log, by the Scribner rule, scales 213 feet, or 5.9 board feet per cubic foot of unpeeled log.

2. By the elimination of gang saws.
3. By manufacturing in round-edged or "wany" form a large part of the lumber which is to be worked over.
4. By modifying market requirements and usage so as to allow boards of random widths and odd lengths.
5. By admitting short and narrow boards.
6. By modifying standard grading rules to allow defects on ends and edges without seriously reducing the grade of a board.
7. By more careful manufacture and more perfect machinery.
8. By utilizing short boards, slabs, and waste for such articles as matches, toothpicks, excelsior, novelties, and other purposes for which large boards and planks are now used.

Under present economic conditions and until more perfect machinery is devised the following wastes are considered unavoidable:

1. Practically the entire bark (except what may be used in tannin)—13 per cent of the total volume of the log.
2. Kerf—10 per cent of the total volume.
3. Loss from edging and trimming—5 per cent of total volume.
4. Loss from slabs—5 per cent of total volume.
5. An additional 1 per cent for unavoidable accidents.

Total necessary waste, 34 per cent of total volume of log, which leaves an unnecessary waste incurred under present methods of over 15 per cent of the total volume. In other words, over 30 per cent of the present waste is unnecessary and can be avoided.

Part of the waste is relative, but it is roughly estimated that the part utilized represents only 8 to 9 per cent of the value of the lumber which the waste represents.

WASTE IN MANUFACTURE OF VENEER.

The main sources of waste in the manufacture of veneer are as follows:

1. Trimming defective ends—3.5 per cent.
2. Loss through checks and cracks—6 per cent.
3. Loss through damaged sap—3.2 per cent.
4. Loss of cores—3.1 per cent.
5. Loss through breakage—5 per cent.
6. Loss through imperfect drying—4 per cent.

The total from sources mentioned is 24.8 per cent of the lumber manufactured.

In addition there is a loss of at least 5.2 per cent from miscellaneous sources, such as kerf in sawed veneer, carelessness, miscut veneer, etc., bringing the total loss up to about 30 per cent. This is equivalent to a loss of over 100,000,000 feet of the 348,000,000 feet manufactured into veneer in 1907.

WASTE IN MANUFACTURE OF COOPERAGE.

The main sources of loss in the manufacture of cooperage are:

1. Allowing logs to dry and check in the woods.
2. Cutting logs into bolts and allowing an overrun of one or more inches in the length of each bolt—7.7 per cent.
3. Improper bolting and the conversion of bolts into staves.
4. Carelessness in stave jointing.

5. Seasoning the finished product—about 4 per cent.

Although no detailed figures for the loss incurred through each of the above sources are available, yet it is estimated to be 40 to 50 per cent of the sound lumber, or, assuming an average of 45 per cent, 56,250,000 board feet on the 1,250,000,000 board feet used for cooperage stock in 1907.

The method of reducing the loss is through greater care in the various processes of manufacture, better and more highly specialized machinery, and a more thorough utilization of the waste.

An attempt has been made in this paper to point out the usual source of waste in converting logs into lumber. At least a part of this waste is shown to be unnecessary. Most of the waste is due to the low value of lumber when compared with other factors of production, such as cost of labor, freight rates, etc. With the growing scarcity of wood and its consequent rise in value ways will be devised for reducing the waste. As long as it is not possible for the Government to exercise a control over the use and misuse of the natural resources, an unnecessarily heavy waste may be expected all along the line.

WASTES AND LOSSES IN MILLING.

INTRODUCTION.

In converting trees to usable shape and form, whether the form be firewood, boards and plank, dowels, or veneer, there is entailed a certain amount of waste, which varies mainly with the form of the product and the value of the wood.

Loss and waste should be distinguished. Loss occurs when material is sacrificed because it can not be used with profit. Waste occurs when only a part of the possible marketable product is extracted; it may be due either to carelessness or ignorance.

This paper will consider the wastes and losses involved in milling. It will consider the log from the beginning, carry it through the various processes in the mill, and show the waste at each operation. In addition, a brief description will be given of the waste connected with the converting of logs into cooperage and veneer stock.

The figures used are taken mainly from two sources. The first of these are mill tallies made by the Forest Service in various regions for the purpose of determining the amount and grades of lumber cut from different sized trees; in connection with this work some 40,000 logs of a dozen different species were measured in the woods and followed through the mill. As to the second source, circular letters were sent to 2,000 of the leading mill men in the country; replies were received from 540 manufacturers whose operations represent an annual cut of 7,121,000,000 board feet. In addition, a circular letter was also sent to 800 cooperage and 250 veneer makers.

Very often wastes can not be expressed in exact figures. The waste due to careless handling of the "nigger" or to the reduction of the grade of lumber caused by careless sawing is of this kind. In such cases care was taken to estimate the waste as accurately and conservatively as possible.

VARIOUS PROCESSES IN A TYPICAL MILL.

It may not be out of place here to give a brief description of the various processes through which a log passes in a typical mill. On reaching the log deck the log is put on the carriage by means of "kickers" and "loaders." It is turned on the carriage by means of a long iron pole fitted with sharp hooks known as the "nigger." As each slab is sawed off the log is pushed forward toward the saw by means of a "setter." The slab is separated from the log by the "off-bearer" and is sent on to the "edger" where the waney edges are sawed off and the edged board goes on to the "trimmer," which cuts or trims off the ends and reduces the boards to a standard length. The boards are then "inspected" or graded and sent to the lumber yard where they are stacked and seasoned, either in the open air or in a dry kiln. Almost every one of these steps involves some waste.

WASTE IN SAW KERF.

One of the chief wastes in converting logs into lumber is saw kerf. This waste varies with the thickness and gage of the saw and the care with which the sawteeth are swaged. It varies also with the thickness of the lumber—the thicker the lumber the less being the amount of kerf in proportion to the size of the log.

The two most common forms of saws used in the United States are the circular saw of 8-gage thickness, swaged to cut about one-fourth inch kerf, and the band saw of 14 to 16 gage thickness, swaged to cut about one-eighth inch kerf. Most of the larger mills are now using the band saw, whereas the smaller mills, especially those that are portable, are equipped with circular saws. There are a great many more circular-saw mills in operation than band-saw mills, but the amount of lumber cut by the two classes of saws is probably the same. The average kerf may, therefore, be assumed to be three-sixteenths of an inch.

An idea of the enormous waste in kerf may be obtained from the following figures: The total production of lumber in the United States during 1907 was approximately 40,250,000,000 feet. The kerf on this lumber, assuming that all of it was cut into 1-inch boards, is equivalent to over 7,500,000,000 feet. To obtain this amount of lumber it would be necessary to cut over an area of about 1,250,000 acres of forest, running 6,000 board feet to the acre, an area almost as great as that of the entire State of Delaware. Figuring that the average annual growth of lumber is 300 board feet per well-stocked acre—a most liberal assumption—the annual loss due to kerf represents the yearly growth of forest on 25,000,000 acres, an area equal to that of either Virginia or Kentucky. That is, if either of these States were covered with an unbroken growth of timber, the annual growth in such a forest would be just enough to compensate for the sawdust.

Since sawdust is, in most cases, used to furnish the fuel to run the mill, it is not an absolute loss. However, with the modern fuel-saving burners the supply usually is in excess of the requirements of the mill. Besides, it is poor economy to convert good lumber into sawdust, even if it is used for fuel, and any saving of waste from this source is greatly to be desired. In a few cases, also, a small portion of the sawdust is sold for packing, stable flooring, etc. It will now be shown that part of this waste is unnecessary and quite avoidable.

The kerf really consists of two parts—the actual width of the sawteeth and the swage of the saw. As mentioned above, the average circular saw used for sawing logs is 8-gage. This represents a thickness of 0.165 of an inch. The actual kerf for such a saw is 0.25 of an inch, the extra 0.085 of an inch being due to "setting" the saw in such a way that it will allow for a proper "clearing" of the log—in other words, to allow space in the cut for the sawdust, and prevent the blade of the saw from binding against the cut surface. Similarly a band saw of 14 to 16 inch gage, representing a thickness of 0.072 of an inch, cuts a kerf of 0.125, an allowance of 0.053 of an inch for "clearing" the log. At least part of this allowance is quite unnecessary. The saving in lumber which may be effected through careful filing and setting is considerable. It probably represents no less than 0.03 of an inch in each cut, or about 3 per cent of the lumber cut.

Unnecessarily thick saws make unnecessary waste in kerf. This brings up the much discussed question of the relative merits of the band and the circular saws.

The claims that have long been put forward in support of the circular saw are that it can be fed faster, that it requires less power, that it is more easily set up and kept in order, and that it does not need the skillful attention required by the band saw. Recent investigations show that these claims have been greatly exaggerated; in fact, that some of them are baseless. It is now generally conceded that in large logs the band saw will cut more lumber in a given time than will the circular, and that the band saw uses less power than the circular saw, doing the same work.

The main point, however, in favor of the band saw is the great saving in lumber which it makes possible. The following table, based on a mill tally of 5,177 white-pine logs cut with a circular saw and 767 white-pine logs cut with a band saw, shows the number of board feet of lumber obtained per cubic foot of peeled log. The lumber was not edged, but was sold "waney" or round edged.

TABLE 1.—*Board feet per cubic foot of peeled log (round-edged lumber).*

Diameter inside bark at small end of log.	Cut with a circular saw.	Cut with a band saw.	Diameter inside bark at small end of log.	Cut with a circular saw.	Cut with a band saw.
Inches.	*Board feet.*	*Board feet.*	*Inches.*	*Board feet.*	*Board feet.*
5	5.5	6.5	13	7.4	8.5
6	6.0	6.6	14	7.5	8.6
7	6.4	6.6	15	7.5	8.6
8	6.7	6.8	16	7.5	8.6
9	6.8	7.3	17	7.6	8.8
10	6.8	7.5	18	7.7	9.0
11	6.9	7.8	19	7.7	9.0
12	7.2	8.2	20	7.8	9.1

The conditions in the mills where the lumber was tallied, on which the above table is based, were very similar, and the difference between the relative amounts of lumber obtained is due almost entirely to the difference between the thickness of the saws.

The saving effected by the band over the circular saw is usually estimated by lumbermen to be 10 per cent of the possible lumber cut. Assuming, as before, that one-half of the 40,000,000,000 feet of lumber produced last year was cut with a circular saw, the saving of 10 per cent would represent a saving of 2,250,000,000 feet (the 20,000,000,000 feet representing only 90 per cent of the amount of lumber obtainable), or the annual growth on over 6,500,000 acres of forest at 300 board feet per acre.

In addition to the loss caused by an undue amount of sawdust, the circular saw entails a loss from another source. The width of the widest board which such a circular saw can cut is equal to the radius of the saw, less about 3 inches (allowed for the collar of the saw). For this reason, even where a 54-inch saw is used, no log greater than 24 inches in diameter can economically be cut with it. When a larger log comes into the mill it is turned on the carriage and slab after slab is pared away until the log becomes small enough for the saw to cut through it completely. This involves not only an enormous waste of the best lumber in the log, but also a great waste in labor. In many instances the plank or slab is only partly separated from the log, and axes are used to cut it off completely.

Measurements made in a mill cutting western yellow pine in New Mexico indicate that the loss of lumber from the use of circular saws too small for the large logs was from 3 to 5 per cent of the entire output of that mill. The loss in value was even greater, since the wood wasted is the clearest lumber in the log. An idea of the time loss may be obtained from the following instance: A log 36 inches in diameter came into the mill. It was figured that under favorable conditions it should have taken from twelve to fifteen minutes to saw it up. The actual time consumed from the time the log was put on the carriage until the last board was taken away by the off-bearer was a little over forty minutes, a loss of at least twenty-five minutes, and for more than an hour afterwards the mill was littered with slabs and chips, and smooth, efficient work was prevented. No definite figures of the loss from this source can be given for the entire country.

Prof. C. A. Schenck arrives at the following conclusions in regard to the relative merits of the band and the circular saws:

> The superiority of the band over the circular saw lies in a saving of 1,000 board feet in every 16,000 feet of -inch boards obtained. The boards have a better width. Logs over 4 feet through can not be handled by circular saws. Further, the band saw allows of a more rapid feed.

The band saw has come into general use in the bigger mills, but the vast majority of mills cutting less than 2,000,000 to 4,000,000 feet a year—in other words, the majority of the small and portable sawmills—are still using the thick circular saws. The main reason for this fact is that it is easier and cheaper to equip a mill with circular saws than with band saws.

The additional waste due to thick saws takes place at the mill, and the loss represents not only a loss in the cost of stumpage, but also a loss in logging and bringing the logs to the mill. In short, it is not only a waste of lumber, but also a waste of labor. With these facts in view, it is only a short time before the band saw will replace the circular saw in all but the very smallest operations.

Mr. Austin Cary, who has been investigating the practicability of the use of portable band-saw mills, has the following to say on this subject:

> The saving in lumber secured by the use of band saws in place of the thicker rotaries is well known. It is usually reckoned by lumber operators as 10 per cent of the cut.

The band saw from the operating point of view is also satisfactory and effective. It uses less power than a rotary doing the same work. It does true and satisfactory sawing if set up right, not overspeeded, and properly handled. As a stationary mill it is for many purposes considered the best and it is securing something of a field in use as a portable. The chief difficulties in its use arise in connection with keeping the saws in order. Much more skill and equipment are required than in the case of the rotary.

Light band mills are employed as portables to some extent in New England and in the South. This paper is written with a view to their use in the western forests.

A type of mill in use for this purpose at the present time carries saws 8 inches wide and 33 feet long, of 16 or 18 gauge thickness, swaged to cut three-thirty-seconds inch or less. The wheels are 5 to 5½ feet in diameter, the upper one adjusted to maintain an even tension at all times. The saw frame entire weighs in different makes from 6,000 to 10,000 pounds, but in transportation is practically taken apart, so that the weight of the heaviest single piece is only about 2,000.

Firm setting is essential to cheap and smooth running and the production of well-sawed lumber. This may commonly be secured by means of posts set in the ground to which the timbers of the mill frame are fastened. If this does not in any case give sufficient firmness, the frame may be further fixed by bracing timbers rising from the ground or timber frame to a bearing on either side at the level of the upper journals.

The carriage and accessories for a mill of this type are very nearly the same as for a rotary used as a portable, an offset to free the saw from the log in gigging back being the only difference. The mill is furnished at the factory with carriage complete up to 20 feet long, set works, friction and cable feed, standard track and wheels, set shaft, and receder for about $1,600. This is about twice the cost of the same equipment for a rotary. An equipment of 6 saws costs $240.

CAPACITY AND POWER.

This mill can cut up to 25,000 feet a day, but run as a portable 10,000 to 15,000 may be counted as its capacity, according to quality of logs. To run such a mill on pine logs, engine capacity of 35 horsepower net is found to be sufficient. An edger requires 10 horsepower additional and a wide planer 25. A 50 horsepower engine of good make with boiler of one-third greater capacity costs in the neighborhood of $1,200. With large logs considerably less power is required to cut the same amount of lumber with the band than with the rotary. With small logs, the rotary requires less power.

FILING ROOM.

It is customary when using the band as a portable to construct a small shanty for filing near the mill, with steam pipe from the main boiler running a small filing-room engine. Where the mill is longer in one place the filing room may be built in the roof of the mill and the machinery run from its shafting. The equipment required is as follows: Automatic saw sharpener, stretcher, adjustable stand and pulleys, filing clamps, shears and retoother, automatic lap grinder, forge, brazing table, swage, shaper.

Total cost of these tools about $600. Total weight about 3,000 pounds. This outfit embraces all that is required to do the fitting and filing by machinery. The oufit may be lessened if certain parts of the process are done by hand.

KEEPING IN ORDER.

A good-sized outfit of saws, six being desirable, is the first requisite for successful employment of the band saw. One set of three may then be kept constantly in order and in reserve for emergencies, while the other three are in use and subjected to minor repairs. Experience and skill are both required to keep a band saw in order. Condition has to be more carefully kept up than in a rotary, though there is this advantage—that apparently bad accidents, such as would destroy entirely the value of a rotary, may be repaired on the spot in case of a band by means of the shears and retoother. Filers for band saws uniformly draw good wages, though good work here pays in quality and output of lumber. It is not necessary, however, to have a special filer for a portable band mill in most circumstances, as the sawyer may occupy this post also, making small repairs to his saws at noon or night and heavier repairs at slack times or between settings. This arrangement has been successfully worked in Massachusetts, and the running cost of operation of a band mill in consequence kept very close to that of a rotary.

TRANSPORTATION.

A band mill for portable use requires the transportation of from three to four tons more than a rotary employed in the same work. There is extra cost involved also in setting up the mill, as earlier explained. In fact, in Massachusetts practice the cost of moving a short distance and setting up is reckoned at twice that for a rotary. This enlarged cost does not hold in the same ratio on long moves, and the larger the amount of lumber to be cut at one setting, the more advantageous the band mill. For set-ups of under 500,000 the band as against the rotary can not be considered on ordinary lumber as practicable. When the amount to be cut is a million or more, the band is considered in Massachusetts advisable. On high-grade, valuable timber the saving secured by the band saw is a far more important matter and smaller set-ups can be profitably handled.

CONCLUSIONS.

The band mill cuts lumber out of anything but the smallest logs with a third less power than the rotary.

It saves 10 per cent or more of the lumber cut, whatever the value of this may be.

The initial expense of a band mill for portable use is greater than a rotary, the figures for the two outfits complete being approximately $2,500 and $4,000.

The band mill is more expensive to move and set up. This makes it impractical for very small amounts of timber.

The band mill requires more skill to keep the saws and machinery in order, but by good arrangements the extra cost of this work may be kept down very low.

Altogether the use of the portable band seems to promise considerable saving and efficiency in the utilization of the timber of the national forests.

When band saws first came into vogue and the advantage of narrow kerf was seen, efforts were made to make the saw thinner and thinner. Experience very soon showed that when the steel reached a certain degree of thinness it did not possess the rigidity necessary to cut straight lumber. But even after this limit was reached a further reduction can be made in the kerf by the introduction of the resaw.

The resaw is either a circular or, more often, a band saw of very narrow gage, and is used to resaw thick lumber cut with the heavier primary saws. There is a double saving in the use of a resaw, a saving in lumber and a saving in the labor of the highly paid sawyer. A skillful sawyer receives from $5 to $10 a day. The grade of labor commonly employed on a resaw is paid from $2.50 to $4 a day. Where a resaw is used the log is cut into thick plank by the skillful sawyer, who gets the greatest amount and the highest grades of lumber possible from the log, and the thick plank is then resawed by the lower-paid resaw man. This is an ideal arrangement, and the millmen are fast beginning to realize it. Out of a total annual cut of 7,121,000,000 feet reported from 540 mills, 4,130,000,000 feet, or 58 per cent of the total, was resawed. The percentage of lumber resawed in the entire country is, however, probably less than 58 per cent of the entire output, since the mills reporting were mainly large mills, and resaws are mostly employed in large mills.

On the other hand, possibly one-fourth of the above named lumber was cut with gang saws. The waste due to gang saws is very large because of the high percentage of lumber which is converted into slabs. The main advantage of the gang saw is the rapidity with which it works. Although no definite data are available it is safe to say that the waste in lumber offsets this gain. It takes little figuring to prove this point. Assuming that the value of the log on the carriage before it is cut is $7.50 a thousand board feet, and that the average wage is $2.50 a day per man, the money represented by a waste of only 1,000 board feet will pay the wages of 3 men for a day. With the extra waste due to the gang saw figured at 10 per cent of the actual cut, a mill with a gang capacity of 100,000 feet a day can afford to employ 30 extra men a day instead of the gang saw. It is very doubtful whether the gang saw saves that much labor.

WASTE DUE TO SLABS, EDGINGS, AND TRIMMINGS.

Probably the heaviest waste in a sawmill is in slabs, edgings, and trimmings. This waste is due to the circular form of the logs, to their surface irregularities and to their natural crook or "sweep." The amount of it depends on a number of factors:

1. The species and age of trees cut. Some species are much more cylindrical and regular in shape than others. Older trees are usually fuller and less tapering than young trees.
2. The position of the log in the tree. The top and butt logs of most species are more tapering than the middle logs.
3. The skill and care of the sawyers in the woods. Judicious division of the tree into logs will largely eliminate crooks and defects.
4. The length of the shortest board considered merchantable.
5. The value of lumber as compared with freight rates. Where lumber is comparatively cheap, while freight rates are high, there will be more slabs and short boards wasted than would otherwise be the case.
6. The care exercised by the sawyer and the other mill hands.

For convenience in describing the waste in slabbing, (1) loss in edging and trimming and (2) loss in slabs will be considered separately.

LOSS IN EDGING AND TRIMMING.

Prof. Judson F. Clark, who, while constructing his International log rule, had occasion to study the question of loss of lumber in edging, states the following conclusions:[a]

> 1. Edging waste remained practically constant regardless of the width of kerf cut by the saw.
>
> 2. It was found that the waste due to crook (major and minor) of all degrees was in direct proportion to the circumference of the logs sawn; i. e., the waste due to any particular degree of crook in a 20-inch log was practically double that caused by a similar amount of crook in a 10-inch log.
>
> 3. When provision is made in the scaling score for an average taper of 1 inch per 8 feet linear, and when the logs show an average major crook of 1½ inches per 12 feet, the necessary allowance for edging waste as above defined was found to be 0.8 foot board measure per square foot bark surface for white-pine logs of all dimensions.
>
> The effect of increasing major crook on the product of sawn lumber was also studied. The results of such a study depend directly on the size of the smallest board which is regarded as merchantable by the investigator, for with increasing crook there is a greatly increased output of short lengths sawn from

---

[a] "The measurement of saw logs," by Judson F. Clark, in Forestry Quarterly, Vol. IV, No. 2, pp. 84–85.

the heavy slabs. The rules of the National Hardwood Lumber Association, the Louisiana Cypress Association, and other similar bodies have set the minimum dimensions of boards entitled to pass inspection and measurement in the case of most species at 3 inches in width by 4 feet in length. Using a minimum unit of just double this size I found that as logs were cut for ordinary commercial purposes in the mill in which I made my tests, an increase in the average major crook of 1 inch per 12 feet increased the allowance required for edging 0.1 foot board measure per square foot of bark surface. With a minimum unit of 3 inches in width by 12 feet in length the additional waste in edging for the same increase in average crook was just threefold, or 0.3 foot board measure per square foot of bark surface.

Although no more definite data than those given above are available on this subject, yet a fair idea of what this loss amounts to may be gathered from Table 2.

TABLE 2.—*Waste in slabs, edging, and trimming.*

Diameter at small end of log, inches.	Edged and trimmed yellow poplar.			Unedged and untrimmed white pine.			Per cent of peeled log wasted, presumably in edging and trimming.
	Board feet per cubic foot of peeled log.	Per cent of peeled log used.	Per cent of peeled log wasted in kerf, slabs, edging, and trimming.	Board feet per cubic foot of peeled log.	Per cent of peeled log used.	Per cent of peeled log wasted in kerf and slabs.

30	7.7	64	36	....	....	....	....
35	7.8	65	35	....	....	....	....
40	7.9	66	34	....	....	....	....

The foregoing table is based on yellow poplar logs which were edged and trimmed at the mill, and on white pine logs which were neither edged nor trimmed. The logs in both cases were sawed with a band saw. The difference in the percentages of waste is presumably due to the waste incurred in edging and trimming. It is seen to vary from 8 per cent for the smaller logs, which are most wasted in slabbing, to 14 per cent in the larger logs.

Since the old yellow poplar is much more cylindrical than the second growth white pine, the loss in slabs, edging, and trimming should have been relatively less in the former than in the latter species. It is, therefore, safe to assume that the minimum waste incurred in squaring boards is 14 per cent of the peeled logs; a very conservative estimate would place it at 10 per cent. This is equivalent to a loss of about 4,500,000,000 board feet in the 40,250,000,000 board feet of lumber cut in 1907.

There is very little unedged timber sold in the United States—in all probability less than 10 per cent of the total output. Deducting 10 per cent from the 4,500,000,000 feet figured above, still leaves over

4,000,000,000 feet lost annually in edging and trimming. Assuming an annual growth of 300 board feet per acre, it would take a solid forest of 13,333,333 acres to produce the lumber wasted annually in squaring boards. This area is almost as great as the combined territory of Vermont, New Hampshire, and Connecticut.

There is no doubt that a portion of this loss is quite necessary and unavoidable, and where this is true, if the loss did not occur at the mill it would be transferred to the consumer or woodworker. Nevertheless, by far the greater portion of the waste is due to the cheapness of the wood when compared with freight rates, and to usage or custom.

A very heavy waste in the manufacture of lumber is caused by standardizing lengths and widths of boards. It is a general requirement of the lumber market that the lengths of boards shall be in multiples of 2 feet. Odd lengths, such as 9, 11, 13 feet, etc., are not admissible except in special orders. The result is that much good lumber is lost through trimming.

A piece of lumber may have a defect at one end making it a few inches shorter than a certain standard length. The board is trimmed down to the next lowest standard length, with a loss of almost 2 linear feet of board.

Similarly with the widths of boards. It is customary with certain kinds of wood, such as white pine, western yellow pine up to 16 inches in width, western larch, etc., to cut the boards in widths which are multiples of 2 inches. With other species, however, as with most of the eastern and southern hard woods random widths are admissible.

The lengths of boards can, to a large extent, be regulated by the sawyers in the woods; i. e., the sawyers can divide a tree without great loss into logs of standard lengths. But the width of boards can not be so regulated. It follows from the law of averages that in the long run the loss in width will be 1 inch when the standard widths are multiples of 2 inches, or one-half inch when the standard widths are consecutive inches. With the average board sawed 12 inches wide this loss would represent a waste of from 4⅙ to 8⅓ per cent of the lumber cut, in addition to loss incurred in edging off the wane. This waste is unnecessary and inexcusable.

What the exact loss is through this source—trimming to standard lengths and widths—it is, of course, impossible to say, but it is possible to make a rough estimate. A study of the grading rules adopted by the various lumber manufacturers' associations brings out the fact that about one-third of all the lumber manufactured is cut into standard widths. Assuming a loss of three-fourths of an inch in width, the average between a loss of 1 inch for even inch widths and one-half inch for consecutive inch widths, and an average width of board of 12 inches, the loss last year due to standardizing widths was at least 2½ per cent of the total output, or a little over 1,000,000,000 board feet of lumber. Two per cent will be taken as the working estimate.

LOSS FROM SLABS.

In addition to the loss in edging and trimming, and closely allied to it, is the waste in slabs. The factors which influence this loss have already been stated. The seventh column in Table 2 indicates the percentage of the peeled log wasted in kerf and slabs. The percentage of kerf is fairly constant for logs of different sizes, and in Table 2 amounts to 11 per cent of the volume of the peeled log.[a] Subtracting 11 from the value given in the column leaves the percentage of the volume of the peeled log converted into slabs. This is seen to vary from 26 per cent for a 10-inch log to 13 per cent for a 20-inch log, the percentage of waste decreasing as the size of the log increases. The average log sawed in the United States is probably less than 20 inches in diameter. This would indicate a minimum waste of 13 per cent in slabs alone. To be conservative this figure will be reduced to 10 per cent of the peeled log, or a total loss of 4,474,000,000 feet for the lumber produced in 1907.

This loss arises mainly from the fact that short and narrow boards can not now be utilized as lumber. In a number of mills observed in various parts of the United States the shortest board that it pays to ship is 8 feet long. The narrowest admissible width is usually 3 inches. Shorter or narrower boards are either cut as lath and batting, or else are used as fuel or burned in the slab burner.

To summarize: There is lost annually through edging and trimming about 10 per cent of the total possible output. An additional 2 per cent of the volume is lost through standardizing sizes, while at least 10 per cent more is lost through slabs, a total loss in slabs, edging and trimmings of 22 per cent.

All of this waste is not an absolute loss. A large part of the slabs and edgings is used for making lath, and in so far as the edgings and slabs are of such size and form that they can not be utilized for any better purpose, their conversion into lath should not be considered a waste at all. To put it differently, the country requires a certain number of lath. This lath can be very economically manufactured from slabs and edgings at a sawmill. As long as the slabs and edgings are more useful for lath than for any other purpose, there is no waste entailed, but a waste occurs when material better fit for lumber is converted into lath.

The production of lath in 1907 was 3,663,600 thousand pieces. It is generally assumed by lumbermen that on an average 1,000 lath can be produced for every 3,000 to 4,000 board feet of lumber manufactured. Assuming that all the lath produced in 1907 was made from slabs and edgings (and there is no doubt that a large percentage of it was cut from logs and bolts), it would have taken an output of only 14,654,400,000 board feet of lumber to yield as a by-product all the lath required by the country last year. This still leaves a waste of the edgings and slabs from over 25,500,000,000 feet of lumber, or from two-thirds of the lumber produced in 1907. A part of the waste, and probably a very small part of it, was converted into pickets and battings, but the fact still remains that about one-half of the slabs, etc., representing a potential output of over 4,500,000,000 feet of lumber was wasted. A part of it, perhaps the larger, was burned under the boilers at the mill, but its use as fuel is very small, when compared with its value as lumber, and the consequent loss entailed is heavy.

---

[a] The lumber was cut with a band saw removing one-eighth inch kerf. The loss in kerf was therefore 1 inch for every 8 inches of boards sawed. This is equal to one-ninth or 11 per cent of the volume of the peeled log.

That a large portion of the waste in trimming to standard lengths is quite unnecessary may be gathered from the fact that the average length of all the pieces of lumber in the ordinary house, including timbers, flooring, sheathing, siding, finish, casings, base, doors, windows, frames, etc., but not including lath and shingles, is less than 4 feet. The average length of all lumber used for every purpose, including the building of bridges, ships, docks, railroads, fences, boxes, houses, etc., is still under 4 feet. Thus large quantities of lumber longer than the average piece used are being used for fuel, because the pieces are considered too short.[a]

Lumbermen throughout the country are fast beginning to appreciate the enormous waste which accompanies the manufacture of lumber, and there is some hope that savings will be effected all along the line. It may not be out of place to give the following extract taken from a paper read by George W. Roper, general manager of the John L. Roper Lumber Company, Norfolk, Va., before a meeting of the North Carolina Pine Association, and reported on page 40 of the American Lumberman for April 7, 1906.

> According to our present method of inspection and grading and under our general rules we are not permitted to ship as merchantable lumber in the rough pieces which are shorter than 10 feet, and are limited to a certain percentage of this length.
>
> I do not believe that the time has yet come in which we can make our merchantable lengths 12 inches and up, but I believe that we can just as well sell No. 1 and No. 2 strips 4 feet and up in length as some others can sell their product in even shorter lengths. When I say 4 feet and up, I do not mean 4, 6, 8, 10, etc., but mean lengths of 4, 5, 6, 7, 8, etc. The barbarous idea, originated by us possibly, of cutting off a board 2 feet in order to cure a 6-inch defect at the end should not, in my judgment, be longer tolerated. There is no reason in the world why the trade would not accept 11, 13, and 15 foot boards as well as 10, 12, 14, and 16. Then, again, if we were allowed to use short lengths could we not often in our woods secure an 8-foot log at the top of the tree which now is lost?
>
> I understand that, in some other classes of wood, there is a grade known as "shorts"—being lumber in lengths of from 4 to 10 feet. This lumber, I am told, is sold log run, or used to be sold that way, for about three-fourths as much as the usual log run, exclusive of the shorts. If we could adopt as our standard lengths for Nos. 1, 2, and 3 lumber 4 feet and up in multiples of 1 foot, and in box grades adopt similarly 6 feet and up, we could expect to get from our sawmills an increase output on an average from our logs sawed about 5 per cent. With a mill cutting 60,000 feet of lumber a day, situated at Tidewater, Va., and assuming the average value of the output a thousand to be $20, which is considerably under that obtained by us at present in my judgment, we would be enabled to gain $60 a day which now is lost. Assuming the mill ran two hundred and fifty days in the year there would be an actual saving of $15,000, which is 6 per cent on an investment of $250,000. If the mill plant is worth $60,000, the saving would represent 25 per cent on the plant investment or the cost of the plant.
>
> Some of our mill plants are making steam now with lumber which ought to be worth $15 a thousand, if we got no more for it than edge-box price. A great many of our mill plants are putting the clearest of their lumber into the slabs, because we do not have a rough-lumber grade which will admit short, clear boards. The clearest lumber that we get is that which is located nearest the outside of the log, and anything that we can do to reduce the merchantable lengths of No. 1 and No. 2 will not only increase the quantity of lumber that we can get out of a log but will also largely increase the percentage of No. 1 and No. 2 lumber.
>
> Two or three of our mill plants, at the request of the writer, have made some experiments in cutting up 12-inch box, edge box and mill culls, in order to

---

[a] See "Looking back on lumber waste," in American Lumberman, August 1, 1908, p. 45.

determine what percentage of No. 1 and No. 2 lumber especially could be secured in shorter lengths, if this lumber was remanufactured with this end in view. From these experiments we have found that in cutting up 12-inch box we obtained over 450 feet of No. 1 and No. 2 lumber, and out of about a thousand feet of 12-inch box there were only, approximately, 175 feet of lumber which should have remained in 12-inch box, or, in other words, only 175 feet out of the thousand did not justify remanufacture. The value of the No. 1, 2, and 3, etc., obtained from a thousand feet of 12-inch box, assuming that we had sale for it, in lengths of 4 feet and up, was very close to $22. The value of 12-inch box is $18.50. This lumber can be remanufactured at a cost certainly not exceeding $1.50, which would leave a clear profit of $2 a thousand to the manufacturer, or 10 per cent, approximately, more than he gets for his lumber now.

In the case of edge box, in the experiments which I had made I found that saving, much to my surprise, even greater than in 12-inch box. Cutting up the edge box in a similar manner to that of the 12-inch there was obtained out of a thousand feet $19.40 worth of lumber, according to the list price. The value of that amount of edge box would have been $15. Adding $1.50 for the cost of manufacture would still leave the manufacturer a profit of $2.90 a thousand on his edge box thus remanufactured, or a clear profit of approximately 20 per cent.

Cutting up a thousand feet of mill culls in a similar manner yielded lumber to the value of $19. Mill culls, I believe, are worth $13 a thousand feet. Adding to this the cost of remanufacture and subtracting from the above would leave a profit of about $4.50 to the manufacturer due to remanufacturing his cull lumber, or a saving of over 30 per cent. The question arises right here, How far can the present North Carolina rough-pine manufacturer enter into the details of cutting up his lumber, and will it pay him? Is it better for him to manufacture a trifle less lumber and get much better returns per thousand feet? Are we not in many instances getting out in our sawmills quantity at the expense of quality, grade, and value of output? These are all serious questions for consideration and there are hundreds of others which I will not mention. If we continue to put our No. 1 lumber into slabs in order to feed it to a hog, that it may furnish steam for our plants, or cut off 2 feet from the end of a 16-foot No. 1 stock because of slight blemish at the end or on account of the log having been cut an inch too short in the woods, there is no law that I know of to prevent this crime! In my judgment the average of us are wasting 5 per cent of the output of our logs, according to present methods. Is this worth anything to us? Are we so prosperous that it does not make any difference?

Practical forestry is beginning to be recognized in our section of the country, and all eyes at this time seem to be turned to the trees which are being fast cut down—the timber resources of the country are being exhausted rapidly. Measures are being taken to replenish in part at least this vast quantity of lumber cut. This is a very commendable movement and one which should receive the encouragement of our association. At the same time would it not be wise for us to undertake to get from the trees which we do cut down in the course of our business all of the lumber that we possibly can, and utilize every portion of them that we reasonably can? As timber grows scarcer such portion of the log as heretofore was waste will be more and more utilized. This condition will necessarily cause many of us to remodel our ancient plants in order that we may not be required to use merchantable lumber in the furnaces to make steam. In olden times the waste was at a maximum. Our forefathers did not begin to use any portion of the wood until they reached the heart. We have increased that portion of the log which is salable until we have almost reached the bark. In many classes of goods which are manufactured now the bark itself is being utilized, and in many places the sawdust as well.

[NOTE.—The figures with reference to the value of lumber used in this article are based on the price list of December 12, 1905. Since that time an increase in the price of lumber simply magnifies the results obtained, as shown.]

WASTE DUE TO CARELESS MANUFACTURE.

The loss in kerf, slabs, and trimmings constitutes by far the heaviest waste in converting logs to merchantable form. At least a portion of this waste is absolutely necessary and should not therefore be considered a waste at all. But there is another source of loss which is unnecessary and which can be easily avoided. This is the loss due to carelessness in manufacture. Hardly any process in the mill is free from it, and when taken for the entire country the waste which occurs is extremely heavy. No definite figures can be given on this subject, but an effort will be made to show how the waste occurs.

In most sawmills when the log reaches the log deck it is put onto the saw carriage by means of "kickers" and "loaders." These are usually iron or steel bars of various shapes, often terminating in sharp points or edges. It frequently happens that logs are broken outright by a careless manipulation of these tools. More often holes are gouged in the sides of the logs, which, although not serious when the bark is still on the log, may entail a considerable waste when the logs come into the mill peeled.

The "nigger" is another frequent cause of waste. The "nigger" is used to put and to turn the log on the carriage. It is a long steel bar or rod fitted with sharp hooks. Unless carefully manipulated the hooks tear the lumber in the log, especially after the log is squared. It often happens when the "nigger" does not work smoothly that the sawyer impatiently pushes it up and down an unnecessary number of times, and violently and repeatedly slaps the log with it. In such cases there is a considerable loss of lumber, for the torn surface of the plank or log must be cut off and thrown on the slab pile, unfit even for lath.

A very heavy loss is caused by setting the log carelessly on the carriage. Most set works are manipulated by means of ratchets. A pin quadrant or scale is attached to a circular slide close to a set lever, graduated in sixteenths of an inch, and having a hole opposite each graduation. A pin inserted in the one indicating the thickness to be sawn limits the travel of the lever, and correspondingly the movement of the set beam of the carriage and the log. After the set works have been used for some time and the machinery becomes more or less worn, one or both of the following things may happen: The hole becomes worn, so that the pin does not fit snugly but gives with the manipulation of the lever; or the pin becomes worn, with the same result. The effect is to move the setting beam too far and to cut the boards thicker than intended. This extra thickness is a total waste, since it is dressed off at the planing mill. The waste is cumulative and may amount to from 3 to 5 per cent of the output. This loss can be obviated by a frequent inspection of the machinery.

The effect of careless sawing, edging, and trimming is admirably stated by E. A. Braniff.[a]

> The profits of milling depend to a considerable extent upon the sawyer, the edgerman, and the trimmer. Many mill owners make the mistake of gauging their sawyer's ability entirely by his speed. It is he who sets the pace for the mill crew and they must keep up with him; therefore every extra thousand feet cut reduces the average milling cost. Broadly speaking, however, what the average sawyer gains in speed above the normal cut he loses in the quality of his product, especially if he is sawing valuable timber, such as yellow poplar. In order to get the best results the sawyer must take time to look at his log and turn it on the carriage as often as necessary. The sawyer whose sole

---

[a] "Grades and amount of lumber sawed from yellow poplar, yellow birch, sugar maple, and beech," Bulletin 73, Forest Service, pp. 21–22.

aim is to make a big cut is the most expensive man the mill owner can employ for the work.

Rapid sawing necessitates rapid work at the edger and trimmer. Much may be lost by inefficient men at these machines. They handle several thousand boards every day, each of them a separate problem which must be solved instantly. The loss of 1, 2, or 3 cents on a piece of lumber by improper edging or trimming is not much in itself, but when these mistakes accumulate, the aggregate per day is often enough to pay the workman's wages several times. The edgerman has no time to stop and make calculations for each separate board. He stands in front of a stream of boards which he must feed into the machine as fast as the live rollers bring them to him. He can, however, be made so thoroughly familiar with the principles of his work that a glance at a board as it comes to him will usually be enough to tell him what to do with it.

The loss entailed in working night shifts and the waste incurred in unduly large mills are closely allied to the waste due to carelessness.

It sometimes happens that owing to a special rush order, or because the logging operation is far ahead of the milling operation, a night shift will be put in the mill for the emergency. In such cases, since it is almost impossible to obtain a complete crew of mill hands for a short time, the regular crew is split up, with the result that the night shift consists mostly of second-class men, while both shifts run short handed. The regular setter then becomes the sawyer, the dogger takes the place of the setter, the slab cutter may be advanced to the position of trimmer, and so with the rest of the men. The waste which occurs through such an arrangement is very great, for not only are the hands not expert enough to do the work, but the fact that the crew is smaller than normal adds to the waste and the confusion. In one mill observed it was estimated that the waste caused by putting on a double shift for two weeks amounted to about 15 per cent of the total output for the two weeks' night work.

Some mills work a double shift regularly, and the loss is not so great. Still even here the listlessness of the night workers will cause greater waste than would be the case with an all-day crew, besides an output of more poorly manufactured lumber.

It is generally assumed by mill men that lumber can be manufactured $2 per thousand cheaper by working double shifts, because with a given fixed capital there is a double output. This assumption does not take into consideration the additional waste and the additional wear and tear on the machinery which, in the long run, may nearly offset the gain.

It is now conceded by most mill men that very large sawmills are not economical, i. e., it pays better to operate two medium-sized mills than a single large mill, since it is difficult to take care of the output of the large mill. The waste of lumber at a large mill is proportionately greater than in a medium-sized one.

The waste caused by carelessness in manufacture, by working night shifts, and by the operation of unduly large mills, when taken for the entire country may be very conservatively placed at 4 per cent of the total output, though, from its very nature, no definite data can be collected on this subject. As already said, this waste is unnecessary; it is mainly an absolute waste, although a small portion of it may be utilized for lath and shingles.

WASTE IN GRADING.

The bulk of all the lumber manufactured is graded by standard rules, adopted by the various lumber manufacturers' associations.

The difference in value between two consecutive grades varies from $3 to $10 or more per thousand feet. According to present grading rules the class of a board may be increased one or two grades by a judicious trimming or edging. In other words, the actual money value of a board is increased if part of the board is cut off and thrown away. To take a specific example: A yellow poplar board 16 feet long and 21 inches wide, containing 28 board feet, has, besides a few small scattered knots equivalent to two standard defects, one large knot about 8 inches from one end. According to the grading rules of the National Hardwood Lumber Association the board will be classed as No. 1 common, and be worth, at $23 per thousand board feet, a little over 64 cents. By trimming off the large knot and (according to the standard length rule) reducing the board to 14 feet in length, containing 25 board feet, the board is raised to the firsts and seconds grade, which commands a price of $44 a thousand for boards more than 18 inches in width. The value of the board is now $1.10. By sacrificing 3 board feet the value of the board was almost doubled. Yet the board was not really changed in character, and nothing was added to it which it did not already have. On the contrary, part of a board having in itself some value was thrown away. This is perhaps an extreme case, but illustrates admirably the heavy premium put on waste by the present grading rules. The waste due to this source was included in the loss through edging and trimming. It is emphasized here merely to indicate a possible saving. There is no doubt that the loss amounts to from 3 to 5 per cent and can be entirely saved. Pressure should be brought to bear on the grading bureaus of the various associations to revise their rules so that no premium will be put on waste of lumber.

THE LOSS OF THE WASTE.

So far, the question of waste has been considered chiefly from the point of view of lumber production. That is, if a portion of log fit for lumber were converted into sawdust or slabs, it is classed as waste. Such may be entirely necessary, as in the case of a certain minimum percentage of kerf without which no lumber can be manufactured, but in so far as it is converted into sawdust when it might have made boards and plank. All kerf is waste of lumber (it is an actual, though necessary waste). It is now in order to consider the loss of this waste material.

Sawdust is almost a total waste. Most of that which is used is as fuel under the boilers; part of it goes into the slab burner; a very small fraction of it is sold for stable bedding, ice packing, etc. Of the cut of 7,121,000,000 board feet of lumber reported in answer to the circular letters already mentioned, only about 2½ per cent of the sawdust produced was used for other purposes than fuel. A large percentage of the sawdust is left in heaps in the woods because there is absolutely no demand for it. The question of utilizing the sawdust and waste slabs is discussed by Doctor Bristol in his report to the Commission.

As has already been shown, slabs and edgings are partly used in making lath. Most of them, however, as well as most of the trimmings, are used as fuel or are entirely wasted. This waste is not necessary. Part of the slabs should be sold as boards, while of the material unfit for lumber the greater portion should be utilized for purposes requiring small dimension stock. A long list could be given of articles which might be made from this waste, most of which are now being made from lumber better fit for other purposes; the more common articles are matches, toothpicks, excelsior, spools and bobbins, dowels, pail handles, clothespins, wooden dishes, toys, and novelties, the smaller sized packing boxes, shoe pegs, and skewers. The Forest Service is about to undertake a study of these industries with a view to suggesting a closer utilization of the present mill waste. It is not at all impracticable to use the slabs and edgings of certain species of wood, such as hemlock, spruce, etc., for pulpwood. The sawdust and slabs of other species, such as chestnut, chestnut oak, etc., may be used for the extraction of tannin. A small percentage of waste is already utilized in this manner, but much more can be used if only the mill men could get into touch with the tannin and pulp men.

WASTE OF BARK.

In the above calculations the waste is expressed in percentage of the volume of peeled logs. But the bark itself constitutes a large percentage of the log, and, since very little use has been discovered for bark, the loss of it may also be considered a waste. Table 3 shows the volume of the bark expressed in percentage of the total volume of the log.

TABLE 3.—*Percentage of bark in total volume of logs.*

Species.	Per cent.	Species.	Per cent.
Lodgepole pine	6	Chestnut [a]	13
Western hemlock	10	Red oak [a]	13
Eastern balsam	10.5	Yellow poplar [a]	13
White pine	11	Western yellow pine	15
Eastern (red) spruce	11	Douglas fir (second growth)	16
White oak [a]	12	Douglas fir (first growth)	20
Loblolly pine	13	Sugar pine	20

[a] Mostly estimated.

Hemlock bark has long been a valuable article of commerce, since it is extensively used in leather tanning. In fact, up to five or ten years ago in certain parts of the United States, the bark was the only portion of the hemlock used, for the lumber was not considered merchantable. Chestnut bark and the bark of certain oaks is also valuable for tannin. The bark of the other species of trees is, however, considered valueless and is left in the woods or sent to the slab burner.

WASTE IN MANUFACTURE OF VENEERS.

Statistics show that 348,000,000 board feet, log scale, were manufactured into veneering in 1907. Although very small when compared with the amount of wood manufactured into lumber, and only about one-fourth of the amount converted into cooperage stock, yet it represents the annual growth of a well-stocked forest of 1,160,000 acres, growing at the rate of 300 board feet per acre per year. The waste entailed in the manufacture of veneer is also very large, and a saving of this waste is greatly to be desired.

Veneers are cut either with a saw or with a knife. If a knife is used, the veneer is either sliced or rotary cut. In the first case the log is usually stationary and the knife slices off thin layers of wood. If rotary cut the log is revolved slowly against a stationary knife. Answers received to a schedule of questions sent to the leading veneer men show that 88 per cent of all the veneer made in 1907 was rotary cut, 6 per cent was sliced, and 6 per cent sawed.

The chief sources of waste are as follows:

1. Defective ends on the logs cause ragged edges on the veneer, which must be cut off. This waste, as reported by the veneer men, amounted to 3.5 per cent of the lumber used.

2. Checks and cracks are serious defects, since it is almost impossible to use such logs for veneering. The waste from this source is 6 per cent of the lumber used.

3. Damaged sap that must be trimmed off constitutes a waste of 3.2 per cent.

4. In rotary cut veneer the core of the log, usually over 6 inches in diameter, can not be cut into veneer. As reported by the veneer manufacturers, the cores represented 16.5 per cent of the lumber used. Most of the lumber represented by the cores was utilized in one way or another, usually for some cheap product for which an inferior grade of lumber could have been used. In some mills, however, the core is used only as fuel for the furnace or is not utilized at all. Reports show a total waste from this source of 3.1 per cent of the lumber used for veneer.

5. Veneer from its very nature is very fragile, and unless it is carefully handled there is a heavy loss due to breakage. The output of 5 per cent of the lumber used, as reported, was broken in handling.

6. A further loss of from 4 to 5 per cent of veneer is caused by checking, warping, and staining in the process of seasoning.

Thus, from the sources enumerated above, there is a waste of about 25 per cent of the total lumber used in this industry. An additional loss of 5 per cent may be safely allowed for other wastes, such as carelessness, etc., bringing the total loss up to 30 per cent.

There is no doubt that part of this waste can be saved by more careful manufacture, while a part of the necessary waste may be utilized in various ways.

WASTE IN MANUFACTURE OF COOPERAGE.

About 1,250,000,000 board feet of lumber were used in the cooperage industry in 1907. Of this amount about 500,000,000 feet were used for tight and the rest for slack cooperage.

The following extract, taken from a Forest Service report prepared by a man who has made a special study of this industry, discusses the loss incurred in the manufacture of slack cooperage and suggests methods of saving the waste:[a]

> Waste in the manufacture of any highly specialized wood product seems to be a necessary and unavoidable evil, and the manufacturer of slack cooperage is perhaps not more wasteful than his fellow wood users. Though probably as much as 40 to 50 per cent of the round timber is unused in the manufacture of staves and hoops and about 75 per cent in the manufacture of

---

[a] Unpublished report on "Woods for Slack Cooperage and their Economic Utilization," by J. J. Levison, pages 14–19.

heading, only part of this loss can be prevented. The waste is not due to one particular cause but rather to a large number of small causes, which in the aggregate amount to considerable.

The cooperage man must have green timber, and yet hundreds of logs or blocks will often be allowed to lie on the yard or in the woods until they become too dry or too checked for cooperage purposes. In Ohio a log is considered green which has been cut five months or less, or until it begins to shed its bark.

At the mill there is often great waste in cutting logs into heading lengths when they are intended to be cut into stave lengths. Heading blocks will often be cut 21 inches long when only 17½ or even 15 inch heading will be circled out of them, and the matcher, in his haste or carelessness, will also frequently cause another waste of 2 inches by the wrong choice of boards. When logs intended to be used for staves are cut in the woods into lengths in multiples of 32 inches and then found when they reach the mill to be unsuitable for staves they are divided into 21-inch lengths and used for heading. This will cause a waste of 3 inches in a log that was cut for six stave lengths, and a waste of 13 inches in a log that was cut for five stave lengths. In the latter case there will be a wasted piece which is too short for a heading block and which will go into the waste pile. To prevent this waste, there is need of intelligent supervision and knowledge on the part of the woods foreman as to the purpose for which each log is best suited. Many logs are also cut a few inches too short in the woods, and the last block must be thrown out at the mill. The logs can often be cut longer, either by going a little higher into the top or by cutting a lower stump.

Improper bolting for staves is another cause of considerable waste. In many mills, instead of being first cut into short blocks and then into bolts, the whole log is first sawed lengthwise into "cants" (sections) and then divided into the requisite short bolts. As generally practiced, this method does not give bolts of the proper slanting form. Moreover, the grain of the log does not generally run parallel to its axis for the entire length, so the bolts cut by the canting method will be more or less cross-grained and hence produce an inferior grade of staves and cause a greater waste.

The preparation of bolts by splitting instead of sawing, still practiced at a few southern mills, is also wasteful one. The fibers of a split bolt generally run parallel to its axis, while the straightness of the grain of a sawed bolt depends upon the skill of the man at the bolting saw. The bolter is apt to produce a cross-grained bolt which will give rough staves, but the waste thus caused is small compared with that which always results from the split bolt. At least the first two and the last two staves in every split bolt have to be discarded because the sides of the bolt are uneven, so that for a given volume of timber sawed bolts will produce more staves of good quality than can be obtained from split bolts.

Carelessness in stave jointing is a very common occurrence and produces much waste. A hard wood with many knots will often cause the jointer to cull hundreds of staves, the defects of which could have been cut around and the staves saved.

After the staves have been manufactured there is a very considerable amount of waste in seasoning. Correct piling is an important factor in both air and kiln drying, and close attention to it would save much stock.

The utilization of the unavoidable waste is a problem which sooner or later will confront every manufacturer of wood, and an early consideration of the subject is most advisable. Whether the loss be due to the oversight of the manufacturer or to the nature of the process, the quantity of discarded wood in slack cooperage manufacture is great, and a considerable proportion of it, such as slabs, culled blocks, and hoop planks, could be rescued from the waste pile at a profit. In many cases the slabs could be used for sawed hoops at a reasonable gain and the culled and broken hoops could be turned into head liners. There is also a possibility that the culled blocks and hoop planks could be made into dimension stock or some other salable product.

The first concern of the cooperage manufacturer should be to prevent the waste as far as possible, and this should start with the cutting of the tree in the woods where a determination as to the purpose which the log will best serve is fully as necessary as a careful working up later.

A great saving of waste can be made in many cases by bettering the methods of manufacturing and handling the stock. The lack of a combined stave, heading, and hoop mill causes much waste. In order to utilize every log and give each one its most economic place, there must be a combination of at least stave and heading manufacture. A log that will not make a good hoop will often make good staves, and one too poor or too small for staves will often turn out excellent heading. But the numerous mills that make only one kind of stock are compelled to throw out unsuitable logs, blocks, and planks that could have served a useful purpose in some other branch of the slack-cooperage industry. Not only should there be, as far as possible, a combination of the various branches of the industry, but as well a careful selection of the machines in the mill and careful attention to their operation and maintenance.

The utilization of the waste pile is a possibility that the local markets and the labor question must, in a large measure, determine. In some localities the waste is selected and sold to factories for the manufacture of wooden novelties, such as shoes, toys, spools, toothpicks, clothespins, and the like. Further investigation may develop the economic possibility of using other parts of the waste for distillation or for pulp. The use of spoiled finished staves as substitutes for shingles on cheap buildings is suggested. Such of the waste as can not be put to any of these uses will supply fuel, and is so used in several mills, the ashes being sold locally for fertilizer, or shipped to be mixed with southern phosphates.

From the above extract it may be seen that Mr. Levison's conclusion that from 40 to 50 per cent of the round timber is wasted in the manufacture of staves and hoops, and as high as 75 per cent in the manufacture of heading, is not exaggerated.

Although the cooperage manufacturers realize that there is a certain loss of lumber incurred in their industry, yet few realize how large this loss is. In a schedule of questions sent out to the leading cooperage men the following was included: "Comparing the volume of the logs or bolts used with the volume of the product, what per cent of material is wasted in the manufacture of staves?" The answer to this question varied from 2 per cent to 66 per cent. The next question on the schedule, "In what way, if any, is this waste utilized?" brought an almost unanimous answer, "For fuel."

Answers to another question on the schedule bring out the fact that, on an average, slack stave bolts are cut 2 inches longer than the staves are to be. Assuming an average length of stave of 24 inches, there is a loss of one-thirteenth of the bolt length, or 7.7 per cent of the total lumber cut for staves.

A heavy loss is also entailed in seasoning cooperage stock. Eighty-five per cent of the output of slack staves is air-dried and 15 per cent is kiln-dried. The loss in air-drying comes from warping, checking, and staining, and amounts to about 4 per cent, on an average. Almost all the loss in kiln-drying occurs from warping, and amounts to but 1 or 2 per cent.

Forty per cent of the slack heading produced is air-seasoned, 60 per cent is kiln-dried. The loss through warping, checking, and staining in the first case averages 5 per cent. If kiln-dried, it amounts to only about 3 per cent. This indicates a loss of from 3 to 4 per cent in seasoning slack cooperage stock.

Of tight staves 40 per cent are kiln-dried, with an average loss through checking, warping, etc., of 2 per cent, and 60 per cent are air-dried, with an average loss of 6 per cent.

Tight heading is half air-dried, half kiln-dried. The loss in the first case is 5 per cent, in the latter case it is only about 2 per cent. The average loss incurred in drying tight cooperage is therefore about 4 per cent.

The methods of reducing loss in cooperage are (1) through greater care in the various processes of manufacture; (2) better and more highly specialized machinery; and (3) a more thorough utilization of the waste.

WASTE IN USE OF TIMBER.

By McGarvey Cline,
United States Forest Service.

INTRODUCTION.

The following discussion is based upon data compiled by the Bureau of the Census and upon reports furnished to the Forest Service by lumber dealers and manufacturers representing the larger lumber-consuming industries. A rather careful search through the lumber trade journals and library references disclosed very little information on the subject of this report. In many cases the data secured were not complete enough to be more than indicative; the discussion, therefore, is only to be regarded as an effort to present the best material available.

CONSUMPTION OF LUMBER BY DIFFERENT INDUSTRIES.

Reports received from 36 railroads, representing 37 per cent of the total railroad mileage of the United States, show that the various lines reporting used, in 1907, 417,800,000 board feet of lumber for car building and 183,600,000 board feet for bridge timbers. Assuming that this same rate of consumption applies to the total mileage (210,000 miles) the railroads of the United States in 1907 consumed 1,128,000,000 board feet for car building and 496,000,000 board feet for bridge construction. In addition to this, 1,155,000,000 board feet of sawed cross-ties were used; these various items making a total consumption, during 1907, of 2,797,000,000 board feet, 7 per cent of the total lumber cut for that year. It must be remembered that this discussion of lumber consumed by the railroads applies only to sawed lumber and does not include the enormous quantity of forest products used in the form of hewed ties, piling, and poles.

Table I contains data taken from Part I of the Census of Manufactures of 1905. At the bottom of the table the matter contained in the various columns is described. The classification of industries, shown in column A, is that given by the Bureau of the Census. The figures in column B show the cost of the raw material consumed by the different industries. Column C gives the average value of the lumber consumed in dollars per thousand feet board measure. These values are based upon the prices of lumber prevailing in 1904. Column D is secured by dividing the figures in column B by those in column C.

Table I.—*Consumption of lumber by wood-using industries in 1904.*

Lumber-using industries.	Cost of material used.	Average price per 1,000 feet B. M.	Lumber consumed, millions of board feet.	Lumber consumption in per cent total lumber cut.
Furniture and cabinet work:				
Furniture	$60,861,123	$16	4,300	12.60
Coffins	9,156,299	14	655	1.92
Billiard tables	885,676	17	52	.15
Picture frames	4,825,702	16	300	.88
Refrigerators	3,086,886	14	220	.64
Sewing machines	2,266,628	16	141	.41
Show cases	2,254,787	16	141	.41
				17.01
Boxes:				
Cigar	3,366,823	18	187	.55
Packing	31,397 410	12	2,610	8.00
				8.55
Agricultural implements	18,200,000	16	1,140	3.30
Carriage and wagon manufacturing	10,338,000	20	516	1.50
				4.80
Ship building	6,700,000	12	558	1.64
Miscellaneous:				
Artificial limbs	122,942	18	68	.02
Lasts	689,103	16	43	.13
Matches	3,142,750	12	220	.76
				.91

Assuming that the building trades consume all the lumber not included in the above estimates, Table II gives the distribution of the lumber cut of 1907 among the principal wood-using industries both in board feet and in percentages of the total cut. This table also assumes that the percentage of the total lumber cut consumed by the different industries, listed in Table I, was the same in 1907 as in 1904. Undoubtedly this assumption is not entirely correct, but it is thought that the relative quantity of material used by the different industries would change only slightly during a period as short as three years.

Table II.—*Showing division by industries of total lumber cut, 1907.*

	Per cent of total cut.	Million board feet.
Building trades	60.0	24,150
Furniture	17.0	6,840
Boxes	8.6	3,460
Railway and transportation	7.0	2,820
Implement and vehicle	4.8	1,930
Shipbuilding	1.6	644
Miscellaneous	1.0	402

KINDS OF WASTE.

A study of the wastes associated with the industrial use of lumber may be divided into three classes:

1. Wastes in seasoning.

2. Wastes in manufacturing, or factory wastes.
3. Wastes due to improper use.

The third class of wastes is so interwoven with general economic conditions that it is almost impossible to deduce any definite conclusions regarding them. They will, therefore, not be considered in this discussion.

BUILDING TRADES.

The building trades, especially in the great lumber-consuming regions, secure practically all their lumber through wholesalers. Table III is based upon reports received from 340 architects. Columns 1, 2, and 3, respectively, under the sections of States, represent materials specified for high-priced, medium-priced, and cheap buildings. At the bottom of each column the number of architects reporting is given. The other figures represent the number of times the different woods were reported, expressed in percentage of the total number of reports. For example, it will be seen in Table III-A that out of 425 reports on woods specified for flooring in high-grade buildings in the New England States 41.4 per cent specified oak, 24 per cent maple, and 21.9 per cent yellow pine.

In the Pacific Coast States, out of 61 reports on the same item, 40.9 per cent specified oak, 36 per cent maple, and none specified yellow pine; 17 per cent, however, specified Douglas fir. This table is interesting in that it shows which woods are most used in the various parts of the country for flooring, siding, sheathing, joists, and shingles.

[a] Reported only once.

To ascertain the relative amount of different forms of materials consumed by the building trades, schedules were sent to wholesale lumber dealers in different sections of the country. Replies were received from most of the important markets of the country, but they were not uniformly filled out, and in many cases were incompletely answered. The replies which were sufficiently complete to be used in this report cover 780,400,000 board feet of soft woods and 34,600,000 board feet of hard woods. Table IV is based upon these schedules and shows the aggregate quantity of each species reported and what percentage of this quantity consisted of the various forms indicated by the column headings.

TABLE IV.—*Stock handled by wholesale lumber dealers.*

Species.	Total quantity reported.	Common boards.	Inside finish.	Siding.	Ceiling.	Flooring.	Plank and dimension.
Soft woods:	*Board feet.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Yellow pine	348,321,000	21.4	10.5	4.3	3.3	5.2	55.3
Douglas fir	138,434,000	10.6	4.8	4.1	4.1	6.4	70.0
Redwood	107,458,000	6.3	22.6	20.1	4.8	.9	45.3
Northern pine	47,922,000	81.0	10.5	.5			8.0
Spruce	12,000,000	100.0					
Western pine	6,277,000	40.5	18.8	4.6	.5	1.5	34.1
Hemlock	785,000	42.0					58.0
Cedar	337,000			100.0			
Cypress	270,000	92.6	6.3				1.1
Unclassified	117,650,000	18.9	57.0	1.3	.4	1.5	20.9
Hard woods:							
Oak	5,955,000	24.2	.3			.3	75.2
Poplar	3,655,000	45.7	.4	28.1	.8		25.0
Birch	2,589,000	96.6	.4			3.0	
Maple	243,000	28.8				71.2	
Other hard woods	3,565,000	100.0					

Table V is compiled from the same set of schedules. The column headed "Distribution by form" shows that of the soft woods handled 44.7 per cent was finish and siding; 12.6 per cent common boards; 28.6 per cent plank; 14.1 per cent rough dimension. The horizontal column marked "Distribution by industry" shows that 82 per cent of the total soft woods was consumed by the building trades; 2.5 per cent by the furniture factories; 15.2 per cent by the box factories; and 0.3 per cent by the vehicle and implement industry. This table also shows what percentage of the total quantity of each form considered is consumed by the building trades, furniture, box, and vehicle and implement factories. For example, all of the finish and siding reported was consumed by the building trades, while of the soft-wood boards reported 39 per cent was used for building, 5.2 per cent for furniture, 54.8 per cent for boxes, and 1 per cent for vehicles and implements. The lower part of the table indicates in a similar way the distribution of the hard woods handled. From these data on the quantity and form of the material consumed by the building trades, it seems that 50 per cent consists of finish, siding, and flooring; 5 per cent of sheathing and common boards; and 45 per cent of joists, scantling, and dimension.

TABLE V.—*Distribution of material handled by wholesale lumber dealers.*

Form of material.	Distributed by form.	Building trades.	Furniture.	Box.	Vehicle and implement.
Soft woods:	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Finish and siding	44.7	100.0			
Boards	12.6	39.0	5.2	54.8	1.0
Plank	28.6	100.0			
Dimension	14.1	83.0	8.3	8.2	.5
Distributed by industry	100.0	82.0	2.5	15.2	.3
Hard woods:					
Finish and siding	12.0	100.0			
Boards	78.6	50.6	44.4	3.0	2.0
Plank	9.4	21.2	62.3		16.5
Distributed by industry	100.0	53.8	40.8	2.4	3.0
All woods		82.0	2.5	15.2	.3

WASTES.

In the building trades there is always a considerable percentage of waste lumber; therefore, after computing the exact quantities indicated in the plans for a building, contractors add the following percentages to the different items of lumber to cover waste. These figures were secured from various handbooks and from reports received from a few building contractors:

	Per cent.
Joists and scantling (very frequently no waste is allowed in these items)	2
Sheathing:	
Laid horizontally	17
Laid diagonally	20
Siding:	
Drop	20
Laid 4" to the weather	50
Flooring and ceiling, square edge:	
6-inch flooring	11
4-inch flooring	20
Flooring and ceiling, matched:	
6-inch flooring	17
4-inch flooring	20
2¼-inch flooring	33
1¾-inch flooring	40
Shingles:	
Plain roof	8
Gable roof	12

By further classifying the above figures it is found that in the use of finish, siding, and flooring the average waste is about 20 per cent; for sheathing it is 18 per cent, and for joists and dimension 2 per cent. These weighted according to the relative amounts of the various classes consumed give an average waste of 12 per cent in general building operations. It is estimated that from the mill to the consumer there is also 3 per cent waste in seasoning due to checks, stains, etc. The total waste, therefore, in building materials is approximately 15 per cent, which annually amounts to 3,600,000,000 board feet.

FURNITURE.

The lumber consumed by the furniture industry is with few exceptions in the form of board, plank, small dimension, and veneer. Table V indicates that 40.8 per cent of the hard woods handled by wholesale lumber dealers and 2.5 per cent of the soft woods are consumed by this industry, but the larger part of the material used is purchased direct from the mill operators or is manufactured at mills operated by large furniture concerns.

Practically all of the commercial hard woods, with the possible exception of hickory, furnish raw material for this industry. From card reports received from 2,482 furniture establishments in the United States it seems that the woods used, with respect to quantity, range themselves as follows:

	Per cent.		Per cent.
Oak	45	Elm	5
Maple	11	Gum	5
Birch	7	Chestnut	4
Yellow poplar	6	Basswood	4
Beech	5	Ash	3

All others, including walnut, mahogany, pine, hemlock, Douglas fir, etc., 5 per cent.

WASTES.

Reports from 61 manufacturers of different classes of furniture show an average loss of 5 per cent in seasoning furniture woods. Table VI is based on the same reports. It shows the average waste in manufacturing various classes from different grades of lumber. The estimates on waste associated with the use of different grades for any particular class of furniture varied considerably. The table, however, shows the range in the estimates furnished by giving the average of the highest one-tenth and the average of the lowest one-tenth of the total number of reports received on each item.

TABLE VI.—*Wastes in the furniture industry.*

[Based on reports received from 61 manufacturers of different classes of furniture.]

Classes.	Grades used.				
	Uppers, firsts and seconds.	No. 1 common.	No. 2 common.	Mill run.	General average.
Tables:	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Average	22	34	39	32	32
Average high	29	46	47	36	
Average low	13	24	33	28	
Cabinets, desks, china closets, bookcases:					
Average	17	32	....	....	25
Average high	27	55	....	....	
Average low	10	15	....	....	
Chairs:					
Average	22	26	....	....	24
Average high	25	33	....	....	
Average low	15	20	....	....	
Bedroom sets:					
Average	25	31	36	....	30
Average high	25	34	43	....	
Average low	25	28	29	....	

In figuring the percentage of waste, most manufacturers measure up the amount of lumber required, according to the design of the piece of furniture under question, then add to this amount a certain percentage, which experience has shown necessary, depending upon the quality of the lumber to be used. In some cases the species is also considered, since some species contain more knots, checks, etc., than others. The table shows the range in wastes reported.

The grades most commonly used are firsts, seconds, No. 1 common, and No. 2 common.

The deduction from these figures is that 25 per cent is a conservative estimate for factory waste in this industry, or 20 per cent, expressed in terms of material purchased. Both factory and seasoning wastes combined amount approximately to 25 per cent, which represents an annual waste of 1,710 million board feet.

BOX FACTORIES.

Table V indicates that 15.2 per cent of the soft woods and 2.4 per cent of the hard woods handled by the wholesalers are consumed by the box factories. This industry, however, secures by far the largest part of its supply direct from the mill, very often the box factory being run in conjunction with the sawmill or a large planing mill.

Practically all low-priced woods are used. In the New England region white pine is the leading material, although spruce and hemlock, as well as poplar, basswood, chestnut, and other woods are also used. In the South Atlantic States, North Carolina pine is the prevailing material; in the Lake States white pine leads; in the Southern States a great variety of woods are used, cottonwood, gum, and yellow pine being the most important; in the Pacific coast States the western white pine, spruces, and firs predominate.

WASTES.

The loss due to seasoning box material is conservatively estimated at about 3 per cent, and the factory waste, which is generally expressed as a percentage of the actual volume of the material entering the finished box, varies from 10 to 20 per cent, 15 per cent being a conservative average. The combined factory and seasoning wastes would therefore amount to approximately 20 per cent, which represents an annual waste in board feet of 692,000,000.

RAILWAY AND TRANSPORTATION LINES.

The species furnishing the bulk of material used by the railroad and transportation lines are yellow pine, Douglas fir, and oak for car and bridge material; and for ties, in addition to the above, cedar, chestnut, western pine, tamarack, redwood, cypress, and several others in much smaller quantities.

WASTES.

Out of 35 railroads reporting on waste of material in car building, 4 report no waste, 6 report 5 per cent, 9 report 10 per cent, 12 report 15 per cent, and 4 report 20 per cent; this gives a general average of approximately 11 per cent. Out of 33 railroads reporting on waste in bridge building, 8 report no waste, 12 report 5 per cent, 8 report 10 per cent, and 4 between 10 and 15 per cent, with an average of approximately 6 per cent. Out of 30 roads reporting, 15 report no loss due to seasoning, 10 report between 1 and 5 per cent, 2 between 5 and 10 per cent, and 3 between 10 and 15 per cent, with an average of approximately 3 per cent. These averages weighted according to annual consumption give an average total waste of 10 per cent in bridge and car material, which represents an annual loss of 282,000,000 board feet.

VEHICLE AND AGRICULTURAL IMPLEMENTS.

These industries, as indicated in Table V, secure some material through wholesalers, but by far the larger quantity of lumber consumed is purchased in the form of plank, flitches, or small dimension, direct from the sawmills. The species most commonly used are as follows:

Box boards	Yellow poplar, cottonwood, red gum, tupelo.	Reaches	Oak.
Box cleats	Yellow poplar, cottonwood, rock elm.	Standards	Oak, rock elm, hickory.
Box beds	Longleaf pine, birch, oak.	Hounds	Oak, rock elm.
Bed cleats	Oak, rock elm.	Spokes	Oak.
Axles	Hickory, maple.	Rims and fellies	Oak, Osage orange (southern trade).
Bolsters	Oak, hickory.	Hubs	White, red, and willow oak, black and yellow birch.
Sand boards	Oak, hickory.	Doubletrees	Hickory, rock elm, oak.
Poles	Oak.	Singletrees	Hickory, rock elm.
Brake bars	Oak, rock elm.	Neck yokes	Hickory, rock elm.

SEASONING WASTES.

The hard woods used in vehicle manufacture are first air-dried from two to four years and then kiln-dried; accordingly, the loss due to seasoning such stock may be divided into losses due to air-drying and losses due to kiln-drying. The following table gives the total losses due to seasoning rough dimension, plank, and boards of the woods most generally used:

TABLE VII.—*Percentage lost in seasoning.*

Species.	Rough dimension.	Plank.	Boards.
Hickory	11	11	12
Oak	10	10	12
Poplar	12	11	11
Ash	9	11	12
Maple	6	9	6
Pine	10	7	6
Elm	7	8	3

These figures indicate an average waste of 10 per cent in seasoning vehicle and implement woods.

Table VIII is based on 159 reports received from manufacturers of carriages, wagons, wheels, rims, poles, shafts, and gears. The table shows the relative amount of waste in manufacturing the finished articles from different forms of material. For example, the waste in the manufacture of axles from dimension based upon 10 reports averages 16 per cent and the estimates furnished range from a minimum of 6 per cent to a maximum of 26 per cent. It is, therefore, evident that not much significance can be attached to the figures showing average waste. From the data it contains it is estimated that there is an average factory waste of 15 per cent in manufacturing the various parts of vehicles from raw material in the form of dimension, billets, plank, or boards. The total waste, therefore, in the vehicle and implement industries amounts to approximately 25 per cent, representing an annual loss of 482,000,000 board feet.

Table VIII.—*Wastes, vehicles and implements.*

SHIPBUILDING AND MISCELLANEOUS.

No figures are available showing the wastes associated with shipbuilding and other miscellaneous wood-using industries. In some of these industries—for example, in the manufacture of spools, shuttles, toys, etc.—the percentage of waste is very high, but since the relative quantity of material consumed by them is so small, they have little economic significance. It is safe, however, to assume that at least 15 per cent is wasted, representing an annual loss of approximately 157,000,000 board feet.

A general summary of the foregoing discussion is shown in Table IX:

Table IX.

Industry.	Estimated consumption, 1907, millions board feet.	Average percentage of waste.	Annual waste, millions board feet.
Building trades	24,150	15	3,600
Furniture	6,840	25	1,710
Boxes	3,460	20	692
Railway and transportation companies	2,820	10	282
Vehicle and implement	1,930	25	482
Shipbuilding and miscellaneous	1,046	15	157
Total or average	40,246	17	6,923

This total waste of 6,803,000,000 board feet represents 17 per cent of the lumber cut of 1907. It is made up mostly of sawdust, shavings, and small blocks, and nearly all of it is burned under factory boilers or as kindling wood; so in the true sense of the word it is not actually wasted, but merely serves a lower purpose than that for which the lumber was manufactured.

SUBSTITUTES.

The wastes due to improper use of lumber are undoubtedly great, but they are difficult to define or to study statistically. A brief review, however, of materials being substituted for lumber may prove helpful in suggesting what these wastes are and to what extent their elimination will diminish the annual consumption of lumber.

BUILDING TRADES.

The enormous supply of building stones and other raw material used in the manufacture of brick, concrete, etc., undoubtedly insures a very rapid decrease in the use of lumber as a building material. This tendency is already very marked in most of the large cities, and when it is remembered that the building trades consume 60 per cent of the entire lumber production, it seems that they offer the best field for decreasing the present enormous consumption.

RAILWAY AND TRANSPORTATION LINES.

Railroads are already using steel to a large extent in car construction and its use for this purpose is constantly increasing. It is almost universally used in car underframes and, to an increasing extent, for the bodies of both freight and passenger coaches. The Pennsylvania Railroad Company estimates that the total weight of wood in one of its modern passenger cars is not over 400 pounds, while many hoppers and other types of freight cars are built entirely of steel. On practically all of the well-established roads steel and concrete are being used for bridges in all new work except where such work is of a temporary character, and it is the general policy to replace wooden bridges with concrete and steel as rapidly as funds will permit.

FURNITURE INDUSTRY.

In the furniture industry brass and iron beds are to a large extent, used in the place of wooden ones. One manufacturer estimates that approximately 50 per cent of the beds now manufactured are of metal. Some restaurant tables are made with iron or wire supports, and pressed steel desks finished in wood, as well as steel typewriter chairs, and steel file cases are coming into use for office purposes.

PACKING BOXES.

The use of veneer and pulp board promises to diminish the amount of lumber required by the box industry and the tendency to adopt standard sizes is doing a great deal to increase the life of the packing box by making it available for reshipments. In general, however, wood in some form seems to be best adapted to the requirements of this industry.

VEHICLES AND IMPLEMENTS.

On account of the increasing scarcity and consequent high price of woods, such as hickory and oak, commonly used by vehicle makers, many substitutes have been tried. The substitution of metal for wood in vehicle construction is practiced to a limited but slowly increasing extent. Steel for axles, rims, hubs, and wire for spokes and sheet iron for body paneling are used. Metal paneling, however, has the drawback of bending easily. Endeavors to make such substitutions are very often unfavorably received by wagon users on account of the rigid and unyielding character of steel construction.

SHIPBUILDING AND MISCELLANEOUS INDUSTRIES.

Steel is rapidly becoming the exclusive material for constructing the hulls of all kinds of water craft, and such materials as pulp fiber, papier-maché, and various metals are rapidly supplanting lumber for such articles as buckets, toys, artificial limbs, etc.

It thus seems quite possible for the country to adapt itself to a per capita lumber consumption not more than one-half as great as at present.

TAXATION OF TIMBER LANDS.

By **Fred Rogers Fairchild, Ph. D.,**
Yale University.

Chapter I.

INTRODUCTORY.

I. GENERAL PRINCIPLES OF TAXATION.

It is safe to say that nowhere in the whole domain of applied economics do we find such general confusion and such wide discrepancy between principle and practice as in the field of taxation. As an introduction to the study of timber-land taxation, it will be wise to lay down at the outset certain principles of taxation which are fundamental and generally accepted.

Every government requires some revenue in order to carry on its necessary functions. In modern States this revenue comes in the main from taxation. This is particularly true of the United States, where other forms of revenue are relatively insignificant.

Taxation necessarily involves sacrifice on the part of the taxpayer. This sacrifice is justified on the ground of the benefit to the public resulting from the operation of government functions. This principle also is the only correct guide to the proper amount of taxation. So long as the benefit to the public as a whole through the use of wealth by the State is greater than if this wealth were used by the individuals from whom it is taken, the imposition of taxes is justified. Otherwise, taxation is excessive.

The purpose of taxation is to obtain revenue. Incidentally, however, the taxing power has almost universally been used to accomplish certain other desired ends. Well-known illustrations are our liquor-license system, our protective tariff, the federal tax on the notes of state banks, etc. Where such a programme unquestionably increases the public welfare, there would seem to be no objection on the ground of principle. In the same way, taxation at a reduced rate or complete exemption may sometimes be granted in cases where an undoubted benefit to the community will result. Obviously such uses of the taxing power are peculiarly open to abuse and should be strictly limited.

In apportioning the burden of taxation among the citizens, it is a truism to say that taxation ought to be just. It is by no means so easy to define clearly what we mean by justice, or to discover what particular method of apportionment will best secure our ideal. The simplest method is equal apportionment; that is, an equal burden on every citizen. This crude plan has prevailed in primitive times, and it is conceivable that under certain conditions it might work fairly well. Just as soon, however, as the most primitive conditions are past, the unequal burdens caused by such apportionment become intolerable.

A second plan of apportionment is based upon the benefit theory. This plan attempts to collect from each citizen a payment in proportion to the particular benefit received by him on account of government services. But the benefits of government are mainly general. How then shall we measure the benefit to any particular citizen? Those who advocate this theory have generally gone on the assumption that the main function of government is to give protection to life and property. It is therefore assumed that, since the benefit of protection to life may be considered equal and the benefits to property proportional to the amount of the property, a correct apportionment of taxation would require an equal poll tax, with the remaining burden of taxation apportioned among the citizens according to the amount of property owned by each. This is in brief the idea of the benefit theory, a theory which is held in a vague sort of way by many people, and has been rather tenaciously adhered to by the legal profession in the United States.

The benefit theory is based on a number of erroneous premises. In the first place the function of government is not wholly the protection of life and property. Very many functions are performed by every modern State. Examples in the United States are too numerous and self-evident to require mention. There is therefore no ground for the assumption that the benefits derived from government are in proportion to property. As a matter of fact, the persons who are most dependent on governmental services are probably the poor and weak. The rich man is able to defend himself and to protect his property by private servants, watchmen, insurance, etc. In brief, the benefit theory would be unjust and impossible to apply. Among economists and students of public finance it has little standing to-day.

The third theory of apportionment is the so-called contributory theory or apportionment according to ability. The proposition here is to apportion the burden of taxation among the citizens according to each one's ability to pay. It is recognized that the benefits derived from government are general rather than particular, and it is maintained that the necessary expenses should be covered by contributions from all the citizens toward a common end in which all are interested. An analogy commonly referred to is the method of paying the expenses of a church or social club. Put in negative terms, the theory of ability means an apportionment which would result in equal sacrifice. The ability theory is undoubtedly the correct theory of apportionment, and the one that is coming to be generally accepted in theory and practice.

The question still remains as to what is the measure of ability or sacrifice. Ability and sacrifice are psychological conceptions, but the tax administrator must have some definite, tangible basis of apportionment. It is generally agreed that ability is to be measured in some way by the possession of wealth. Wealth exists in two forms: Either as capital, that is, an existing fund of wealth at a particular time; or as income, that is, a flow of wealth or of the services of wealth during a certain interval of time. Tax systems in general may be separated from each other as they apportion the burden, either according to capital or according to income. European countries in general apportion taxes according to income, whereas in the United States the general basis is the possession of capital or property.

II. THE GENERAL PROPERTY TAX IN THE UNITED STATES.

The basis of American state and local taxation is the general property tax. The theory of the general property tax contains two leading propositions: First, that property is a fair index of tax-paying ability, and second, that this index is capable of being estimated. Neither of these premises is correct. The general property tax is one of the oldest forms of taxation. It has always been the chief reliance of the American States and towns. Under the conditions prevailing in the colonial period the theory on which the tax is based was not so far from the facts, and the tax worked fairly well. The colonists were engaged mainly in agricultural pursuits, with some simple manufacturing industries and commercial enterprises. The bulk of the wealth consisted in lands, buildings, and agricultural stock and implements. Such property is easily located and its value capable of fairly accurate determination. Moreover, the relative economic position of different individuals bears a fairly close relation to their possessions. Under such conditions, the general property tax works well; assessment is fairly simple, evasion is difficult, and substantial justice is likely to be secured.

At present conditions are entirely changed. The bulk of wealth is no longer in real estate and visible personalty. To-day a large part of our property consists in stocks and bonds and other intangible evidences of wealth. Under a general property tax every individual is assumed to be assessed according to his total possessions, tangible and intangible. As a matter of fact, intangible personalty very largely escapes. In other words, the general property tax is unsuited to modern conditions. We need not describe the well-known result. Every one is familiar with the practical administration of the general property tax, and the ease with which taxes are evaded is notorious. The tax runs counter to two of the strongest motives to human action, the love of gain and the dislike of publicity. Since evasion is so easy and the motives to it so strong, it is no wonder that the administration of the general property tax has become a farce.

It is often stated that the failure of the general property tax is due entirely to administrative defects; that the tax is correct in theory and would work well if properly administered. This is not true. A general property tax is wrong in principle, and would lead to injustice and inequality even were it possible to administer it perfectly. In other words, the first premise of the general property tax is also false. Property is not a fair index of ability to pay taxes. An illustration of this will appear in the chapter on "The real economic problem of forest taxation."[a]

---

[a] See Chapter V, p. 611.

In conclusion, the general property tax is a failure, historically, theoretically, and practically. Gradually the public is coming to a realization of this fact. Already many of the States have abandoned it in particular cases where its failure has become intolerable, as in the case of railroads, banks, and other corporations. We have practically, though not admittedly, given up the attempt to tax intangible personalty. A growing demand is in evidence for the giving up of the State's share in the general property tax, leaving it solely to the towns and counties. In these and other ways the movement away from the general property tax is unmistakable. In its adherence to this discredited tax the United States stands almost alone to-day. Other countries generally abandoned it long ago. Income, not property, should be the basis of any correct tax system.

Chapter II.

FOREST TAXATION IN THE UNITED STATES: THE LAWS.

Timber lands are taxed to-day under the general property tax in every State and continental Territory of the United States, generally in exactly the same manner as other kinds of wealth. In only twelve States[a] is any special consideration given to timber lands in the tax laws. Four other States[b] make provision for bounties for timber planting and cultivation, though these bounties have no connection with the taxation of the land or trees. Two States,[c] included, however, in the first group mentioned above, attempt to encourage the planting and cultivation of trees by offering prizes, without any reference to taxation. In all of the other thirty States and in the two Territories timber lands receive no special consideration.[d]

I. TAX EXEMPTIONS AND REBATES, AND BOUNTIES DEDUCTED FROM TAXES.

The twelve States whose tax laws make special reference to timber lands attempt to encourage the planting and cultivation of trees or the general practice of forestry by certain concessions in taxation. These concessions take the form of entire or partial exemptions from taxation, of rebates of part of the taxes, or of bounties to be deducted from the taxes.[e] The method usually employed is that of exemption. The plan of a rebate is used by New Hampshire; North Dakota uses bounties, while Wisconsin uses both exemptions and bounties. These exemptions, rebates, or bounties are granted to owners of timber lands in consideration of the planting, cultivating, growing, or protecting of trees, usually in accordance with regulations specified in the statutes, or under the direction of some state officer or board. In eight of the States the law applies only to plantations, and in five

[b] Illinois, Kansas, Minnesota, aid Wyoming.

[c] Massachusetts and Vermont.

[d] For a list of these States and Territories, see appendix to Chapter II, p. 587.

[e] An abstract of the statutes in each of these States will be found in the appendix to Chapter II, p. 587.

States the land must not be wooded at the time of planting or growing the trees. In one State—Connecticut—the exemption applies only to land "not theretofore woodland."

The commonest form of tax concession consists of a complete exemption from taxes on the land and trees for a definite period of time, ranging from five to thirty years. The exemption begins either immediately after the land has been planted or set aside for the growth of trees, or after a certain period, measured either in years or in the growth of the trees.

In other States the concession is by means of a rebate of part of the taxes for a certain number of years (New Hampshire)[a] or by means of a bounty of so many dollars per acre to be deducted annually from the taxes on the land. (North Dakota and Wisconsin.)

In other States the exemption applies to the value of the trees only. (Nebraska and Washington.)

Iowa grants partial exemption to forest and fruit tree reservations by an arbitrary assessment of the land at $1 per acre.[b] Iowa also exempts from assessment the value of all planted trees.

II. BOUNTIES WITHOUT REFERENCE TO TAXATION.

In four States the attempted encouragement to forest planting and cultivation is by means of bounties having no connection with taxation. Strictly speaking, these laws do not belong in a study of taxation. However, since their general purpose is the same as the tax laws described above, and since they have some other points of resemblance to those laws, it has seemed worth while to mention them here for the sake of completeness. In only one of these cases (Minnesota) is a bounty actually offered by the State. The other three States merely give permission to the county commissioners to offer limited bounties.[c]

III. PRIZES.

For the sake of completeness we also mention the two States which provide by law for the offering of annual prizes to encourage the planting and cultivation of trees. The competitions are administered and the premiums granted through associations devoted to agriculture, etc., in the State, and funds are appropriated annually by the State for this purpose. In Vermont the law applies only to maple-sugar products.[c]

IV. CRITICISM.

None of these schemes of exemptions, rebates, bounties, and prizes has touched the real problem of forest taxation. Obviously, laws giving occasional small prizes for the best examples of tree plantations, hedge fences, etc., can have no far-reaching effects on the burdens of taxation. The same is true of the bounty laws of Illinois, Kansas, and Wyoming, which merely permit the several counties to grant small bounties for a few years. The Minnesota bounty law is the only one that has produced any results. Up to 1906, $440,000 had been spent by the State for this purpose, as a result of which it is claimed that some 50,000 acres have been forested.[a] If this result has indeed been accomplished it has been at a tremendous cost. Evidently we will not find a solution to the problem here.

---

[a] Pennsylvania's rebate laws have recently been declared unconstitutional.

[b] Indiana formerly had a similar law, but it has been declared unconstitutional.

[c] An abstract of these laws will be found in the appendix to Chapter II, p. 587.

Something more might perhaps be expected of those laws which really give some abatement of the burden of taxation by means of exemptions, rebates, and bounties. Yet here also we find that practically no results of importance have been produced. Massachusetts has had an exemption law in force ever since 1878. A legislative committee in 1906 reported that this law "has been a failure, as practically no planting has been done under it."[b] One of the members of this committee reports that he could find only 16 acres in the State that had been affected by the law since 1878.[c] With regard to the rebate law of New Hampshire, the state forestry commission reports that "This abatement provision, although 3 years old, is not widely known among landowners, and has so far been inoperative."[d] In Connecticut, the exemption law has been similarly ineffective. Similar reports come from the other States where these schemes have been in operation long enough to have produced any results. The conclusion that these laws have produced no important results is confirmed by the testimony of all who have investigated the subject.[e]

This lack of results may be explained in part by certain very important defects in these laws. In the first place, the common restriction of the tax abatement to plantations, and the further restriction in many cases to land other than woodland, in large measure destroy the usefulness of the laws at the very beginning. The real problem is in connection with, not the planting of new forests on agricultural or other land, but the protection and preservation of our present forests.

Moreover, the regulations regarding planting, thinning, etc., are not drawn in accordance with scientific forestry principles. Often the number of trees required per acre is too large. When the planting is restricted to certain specified kinds of trees, the list is not always well chosen, valuable species being often omitted. The proper thinning of the growing forest and the most profitable use of the forest are often interfered with by the requirements of the statutes.

Again, the burden of the tax reduction is not provided for or not properly placed. The justification of the concession to the timber owner lies in the advantage to the State in general. Yet the particular locality in which the land is located is called upon to bear the whole or the principal part of the burden of a diminished revenue. What the timber owner gains must be made up by heavier taxes on other local property. This point was evidently not considered at all in framing these laws.

---

[a] Report of the Massachusetts legislative committee of 1905 to consider the laws relative to the taxation of forest lands, p. 10.

[b] Report of the Massachusetts legislative committee of 1905 to consider the laws relative to the taxation of forest lands, p. 17.

[c] Akerman. Southern Woodlands. June, 1908, p. 39.

[d] New Hampshire Forestry Commission Report, 1905–6, p. 204.

[e] Cf. Pennsylvania Department of Forestry Report, 1905–6, pp. 15–19; the Massachusetts Report referred to above; etc.

Certain local assessors have taken this matter into their own hands, and have adopted the custom of adding enough to the assessment of some other property of the timber owner to make up for the reduced taxes on his timber lands. In this way they protect the local revenue, and also defeat the whole purpose of the law.[a]

The actual financial consideration in these laws is really not very great. Generally the exemption is limited to a rather short period of time, after which the land and trees are again subject to the general property tax. Moreover, the abatement comes in the years when the trees are small and when the taxes would not be very heavy anyway. The remission of taxes resulting from these laws is small when compared with the expense of planting trees and holding them to maturity.

In short, these laws are based on no sound principles either of forestry or of finance.

It is not to be inferred that the failure of these laws to produce important results is wholly due to the defects just described. It is very doubtful whether any law of this character, no matter how scientifically drawn and administered, short of a complete exemption of growing timber, can have any great influence on forests and forestry.

The effects of all these laws on the actual burden of timber land taxation may be regarded as negligible. We accordingly return to the statement with which this chapter started, that timber lands are taxed in the United States, with few and unimportant exceptions, in exactly the same manner as other wealth subject to the general property tax.

APPENDIX.

LAWS RELATING TO FOREST TAXATION IN THE UNITED STATES.

I. GENERAL SUMMARY.

Special consideration is given to timber lands in the tax laws of 12 States, as follows: Alabama, Connecticut, Iowa, Maine, Massachusetts, Nebraska, New Hampshire, North Dakota, Rhode Island, Vermont, Washington, and Wisconsin.

The States which provide for bounties, without reference to taxation, are four in number, as follows: Illinois, Kansas, Minnesota, and Wyoming.

The States which provide for prizes, without reference to taxation, are two in number, as follows: Massachusetts and Vermont.

No special consideration is given to timber lands in 30 States and 2 Territories, as follows: Arkansas, California, Colorado, Delaware, Florida, Georgia, Idaho, Indiana, Kentucky, Louisiana, Maryland, Michigan, Mississippi, Missouri, Montana, Nevada, New Jersey, New York, North Carolina, Ohio, Oklahoma, Oregon, Pennsylvania, South Carolina, South Dakota, Tennessee, Texas, Utah, Virginia, West Virginia, Arizona, and New Mexico.

This appendix presents an abstract of all state laws which offer inducements to the planting and cultivation of trees by means of tax exemptions or reductions or by other financial considerations. They are arranged according to their subject matter in three groups: (1) Those laws which grant exemptions or rebates from taxation, or bounties to be deducted from the taxes; (2) those laws which grant bounties without reference to taxation; (3) those laws which provide for prizes for tree planting and cultivation, without reference to taxation. Strictly speaking, only those laws in the first group belong to the discussion of taxation. However, the other laws have the same general purpose, and occasionally some other points of resemblance to those in the first group, and it has seemed worth while to include them for the sake of completeness.

---

[a] Elliott. Forestry and Irrigation, April, 1906, p. 178.

The following abstract covers the main features of the statutes, but omits such details as the number of trees required per acre, regulations as to thinning, etc., which are generally provided for in the laws. The abstract is intended to cover all laws in the States and Territories of the continental United States in effect in October, 1908, but it is possible that some enactments of 1908 may have been omitted. Laws clearly held unconstitutional have been omitted.

II. TAX EXEMPTIONS, REBATES, AND BOUNTIES DEDUCTED FROM TAXES.

1. Alabama permits the owner of land which has been denuded of trees, or the assessed value of which does not exceed $5 per acre, to make a contract with the commission of forestry agreeing to plant or grow and maintain timber trees on such land for ten years, under the direction of the commission, in return for which the land is exempt from taxation for a period of ten years. (Laws of 1907, Sp. Sess., No. 90, H. 67.)

2. The Connecticut law applies to any land, not exceeding in value $25 per acre, and not previously woodland, which the owner plants to certain specified kinds of timber trees. After the trees have grown to the average height of 6 feet, the owner may obtain exemption from taxation for a period of twenty years. (General Statutes, Revision of 1902, sec. 2320.)

3. The Maine law applies to "cleared land or lands from which the primitive forest has been removed," which the owner plants or sets apart for the growth of forest trees. After the trees have been properly maintained for three years, the owner may obtain exemption from taxation for twenty years. (Laws of 1907, ch. 169.)

4. The Massachusetts law applies to plantations of certain specified kinds of timber trees, upon land which at the time of planting was not "woodland or sprout land, or land containing more than 600 standing trees to the acre," and not worth more than $10 per acre. After the trees have grown in height 2 feet on the average, the owner is entitled to exemption from taxation for ten years. (Laws of 1908, ch. 120.)

5. The Rhode Island law applies to plantations of certain specified kinds of timber trees upon land worth not more than $25 per acre. Exemption from taxation is granted for a period of fifteen years from the time of planting, provided the land is planted and managed under a forest-working plan approved by the state commissioner of forestry. Not more than 300 acres owned by a single person or corporation may be thus exempted from taxation. (Laws of 1908, ch. 1581.)

6. The Vermont law allows to uncultivated lands, planted to timber or forest trees and cared for under the direction of the forestry commissioner, exemption from taxation for ten years beginning April 1 of the second year after the planting. (Public Statutes, 1906, sec. 368–370; 496, Sub. XIV.)

7. The Wisconsin law applies to lands not within 2 miles of any incorporated city or village except upon written approval of the state forester, and not worth more than $10 per acre. If the owner of such lands sets apart any portion, not exceeding 40 acres, for forest culture and plants it with timber or forest trees, and properly maintains the trees, he is entitled to exemption from taxation for a period of thirty years from the time of planting. (Laws of 1907, ch. 592.) Wisconsin also provides that when tree belts of certain specified character are planted and properly maintained, the land on which they are planted shall be exempt from taxation until the trees reach the height of 12 feet, after which the owner is entitled to an annual bounty of $2 per acre, which bounty is deducted from the taxes assessed on the land. (Wisconsin Statutes of 1898, sec. 1469–1471.)

8. Iowa has an exemption law somewhat different from the others. The Iowa statute provides for the setting apart of so-called forest or fruit-tree reservations in private ownership, with certain restrictions as to area of the reservation, and number, species, and care of the trees. Such reservations are assessed for taxation at $1 per acre for a period of eight years from the time of planting. Moreover, in all cases where trees are planted, the assessed value of the land is not to be increased on account of the value of such trees. (Code of Iowa, Supp. of 1907, sec. 1400c–1400p.)

9. Nebraska has a statute providing that "The increased value of lands, by reason of live fences and forest trees grown and cultivated thereon shall not be taken into account in the assessment thereof." This law carries out a provision of the state constitution expressly permitting such legislation. (Compiled Statutes of 1881 with amendments to 1907, sec. 4934.)

10. Washington exempts from taxation "all fruit trees, except nursery stock, and forest trees artificially grown." (Pierce's Code of 1905, sec. 8595, sub. 5.)

11. New Hampshire allows to the owners of land planted with timber or forest trees the following rebate of taxes for a period of thirty years: For the first ten years after planting, a rebate of 90 per cent of all taxes assessed upon the land; for the second ten years, a rebate of 80 per cent, and for the third period a rebate of 50 per cent.[a] (Laws of 1903, chap. 124.)

12. North Dakota grants a bounty of $3 per acre for tracts of prairie land of 1 to 10 acres planted to any kind of forest trees and properly maintained. This bounty may commence one year after planting and is deducted annually from the farm taxes for a period of five years. A bounty is also granted for forest trees planted in hedge rows as boundary lines. The bounty is $2 for 80 rods of hedge row, paid annually for a period of five years. (Revised Codes of 1905, secs. 2082–2085.)

III. BOUNTIES WITHOUT REFERENCE TO TAXATION.

1. Minnesota gives a bounty of $2.50 "per acre for a period of six years" to any person who plants from 1 to 10 acres of prairie land with forest trees and properly maintains them. (Revised Laws of 1905, secs. 2391–2395.)

2. Illinois allows the county commissioners in any county to offer a bounty not to exceed $10 per acre annually for three years to any person who shall plant and properly cultivate 1 or more acres of forest trees. (Revised Statutes of 1908, chap. 136, secs. 1–4.)

3. Kansas also permits the county commissioners in any county to offer a bounty "not to exceed $10 for five years for each acre" to any person who plants and properly cultivates forest trees. The trees must have been kept in thrifty condition for five years before the bounty is payable. (Dassler's General Statutes of 1905, secs. 8605–8608.)

4. Wyoming has a similar law allowing the county commissioners in any county to offer a bounty "not to exceed $10 for five years for each acre" to any person who shall plant and properly cultivate forest trees. The trees must have been kept in thrifty condition five years before the bounty is payable. (Revised Statutes of 1899, secs. 2645–2648.)

IV. PRIZES.

1. Massachusetts requires that every incorporated agricultural society which receives a bounty from the State shall annually offer premiums to encourage the raising and preservation of forest trees. (Revised Laws of 1902, chap. 124, sec. 10.)

2. Vermont provides an annual appropriation of $500 for the Maple Sugar Makers' Association of the State and requires that at least $100 annually shall be spent by the association in premiums for the best maple-sugar products. (Public Statutes of 1906, secs. 340–341.)

---

[a] Pennsylvania has allowed a rebate of 80 per cent of all taxes on land containing forest trees with certain restrictions as to number and size of trees, etc., provided that the rebate shall not exceed the sum of 45 cents per acre. (Laws of 1905, chap. 88.) Another Pennsylvania law formerly provided that lands planted to forest trees or maintained with sprout, forest or timber trees, with certain restrictions, shall receive a rebate of 80 per cent of all taxes for a period of thirty-five years from the time the land has been planted or maintained, provided that the rebate shall not exceed 45 cents per acre. (Laws of 1905, chap. 179.) The above statutes were enacted in 1905, taking the place of similar laws which had been in force since 1887, but both statutes have recently been declared unconstitutional. (Tubbs *v.* Tioga County, 32 Penn. County Court Reports, p. 504.)

CHAPTER III.

FOREST TAXATION IN THE UNITED STATES IN PRACTICE.

I. ADMINISTRATION.

The foregoing discussion of special statutes relating to the taxation of timber lands has shown how little real importance they possess. None of the statutes providing for exemptions, rebates, bounties, and prizes has modified to any extent the burden of the general property tax, or had any important effects on timber lands and the practice of forestry. In studying the practical administration of forest taxation, we are really studying the general property tax itself. The following discussion of methods of administration is therefore very brief, attempting only to give a general survey of the actual administration of the general property tax under which forest lands are taxed.

The administration of the general property tax, being in the hands of local officers, is not exactly the same in any two States or even in any two towns. No attempt will be made here to describe peculiarities of local administration. Certain broad features, however, mark the administration of the general property tax everywhere.

Assessment is in the hands of local officers representing usually the towns but frequently the counties. It is the business of the assessors to make a valuation of the property of every taxpayer in the town or county. The assessor is ordinarily a man possessing no particular technical skill and having no particular facilities for ascertaining the value of property. He is obliged to depend upon the taxpayer's declaration, upon hearsay evidence of one sort and another, and upon occasional examinations of the property which must be at best superficial and inaccurate. The methods of assessment are usually lax. Personal examination of forest lands is made only occasionally at more or less long intervals. Very commonly the tax assessor makes up his books by merely copying from the books of the year before. Even where the assessor uses the best possible methods and the greatest care, the result is bound to be largely a matter of personal judgment. The opportunity for the exercise of personal prejudice is obvious, as is also the opportunity for dishonest collusion with the taxpayer. It should be said, however, that testimony is almost universal to the fact that the local assessors are as a rule honest and faithful officers who endeavor to perform their duties conscientiously and to the best of their ability. The usual motive to undervaluation—the desire to escape as much as possible of the town's burden of State and county taxes—is present wherever the State and county share in the proceeds of the general property tax. This hit-or-miss method of assessment produces the well-known results of inequality, undervaluation, overvaluation, and general confusion. As a rule all property is assessed considerably below its true market value, although this is contrary to law. Assessors usually adopt some fixed ratio of assessed to true value.

The collection of the tax on timber lands is also in the hands of local officers, and involves nothing of special importance in this connection. The rate of the tax is made up of the state, county, and town rates, with sometimes other rates for schools, roads, etc. In a number of States, however, the general-property tax is left to the local divisions, in which case there is no state rate. The tax rate varies from place to place. The burden of taxation on any piece of land depends on the tax rate combined with the ratio of assessed to true value.

II. THE BURDEN OF TAXATION.

It is important to know just what is the actual burden of taxation upon timber lands. To thoroughly answer this question would necessitate a detailed study of forest taxation in every State, and indeed in every town where forests are important. This study will take time. Only a beginning has been made as yet. Nevertheless, enough evidence is at hand to enable us to draw some conclusions. These conclusions are, however, only tentative and may possibly have to be modified after further investigation. They are based on (1) an extensive correspondence with tax officials, state foresters, lumber owners, and others; (2) special local investigations made by members of the Forest Service; (3) miscellaneous evidence from forestry journals, lumber-trade journals, the publications of the United States Forest Service, and the several state foresters, and from numerous other sources.

From this evidence, so far as it goes, the following conclusions seem to be warranted:

1. The valuation of forest lands is made in the most haphazard way, resulting in the greatest uncertainty and inequality. For example, a wood lot in New Hampshire was purchased for $1,000. Its assessed value, which had been $400, was immediately raised to $3,000, or three times the purchase price. The tax rate in this town was 1.85 per cent. Assuming that the purchase price represented the true value of the property, it was required to pay a tax every year of 5½ per cent of its value. In this particular case the owner made no complaint, for the reason that he believed this excessive tax was counterbalanced by undervaluation of some of his other lots, an interesting commentary on the results of local assessment.

As an example of undervaluation we may cite another piece of timber land in New Hampshire which was sold for $15,000. Its assessed value at the time was $500, or one-thirtieth of the selling price. Even after the sale, its assessed value was raised only to $1,100.

Here is an interesting example of unequal assessment. Two adjoining tracts in New Hampshire were estimated by the Forest Service investigator to be of about equal value. The first, which was if anything the more valuable of the two, was assessed at $500; the second at $3,500, or seven times the other.

2. The above examples are extreme cases, though similar cases are common enough. What we are more especially interested in is the prevailing burden of taxation in the general run of ordinary cases. The facts seem to be as follows: In some States or regions the prevailing burden of taxation on timber lands is undoubtedly very heavy. There is a good deal of evidence showing excessive taxation of timber lands in parts at least of the States of Michigan, Wisconsin, Minnesota, and the States of the Pacific coast. On the other hand, there are States where the prevailing taxation of timber lands is decidedly lenient. Individual cases of unduly lenient and excessively heavy taxation are common, probably everywhere. Leaving out of consid-

eration individual cases, and without going into local conditions, it is safe to say that in general timber land, like most other property, is grossly undervalued by the assessors. Probably, until very recently at any rate, timber land has been assessed relatively lower than agricultural land. This assessment is combined with a high tax rate; that is, a rate which would generally result in excessive taxation if the property were assessed at its true value. As a general rule, however, due to the prevailing underassessment and the lax administration of the laws, timber lands are not subjected to an excessive burden of taxation. In the great majority of cases investigated the annual tax was less (usually very much less) than 1 per cent of the true value.

3. A third conclusion that stands out distinctly is that there is at present in many places an unmistakable tendency toward heavier taxation of timber lands. This tendency is seen especially in those regions where forests have heretofore been admittedly taxed very gently, such as the wild lands in the unincorporated parts of Maine and New Hampshire. Here there is considerable complaint of the escape of wealthy timber owners from their just share of taxation, and a growing demand for amendment to the statutes which will put a heavier tax upon these lands. On the other hand, the movement toward heavier taxation is seen in the common tendency to value timber lands more accurately and enforce the existing laws more strictly. It should be remembered, however, in connection with the tendency to increase the assessed valuation of timber lands, that there has been a very great increase in the real values of lumber and timber lands within recent years.

The evidence on this subject, though far from complete, is still quite extensive. Part of this evidence is presented in the appendix to this chapter, together with some analysis and discussion.[a] Some further incidental light on this problem may be obtained from the testimony of lumbermen presented in the appendix to the next chapter.[b]

APPENDIX.

EVIDENCE AS TO BURDEN OF TAXATION ON FORESTS.

I. SOURCES OF EVIDENCE.

The conclusions in the text regarding the present burden of taxation upon forests in the United States are based upon a mass of evidence, the principal sources of which are the following: (1) Letters from local tax assessors and other officers received in reply to a schedule of inquiry sent out by the Forest Service under the writer's direction; (2) letters from state foresters, tax commissioners, and other authorities received in reply to a letter of inquiry sent out by the International Tax Association; (3) special local investigations made by members of the Forest Service; (4) miscellaneous evidence from forestry journals, lumber-trade journals, and publications of the United States Forest Service and the several state foresters; (5) an extensive correspondence by the Forest Service and by the writer; and (6) interviews with a number of persons having special knowledge of the subject. In this appendix is presented, with some analysis and discussion, some of the more important parts of this evidence.

---

[a] See Appendix to Chapter III, p. 592.

[b] See Appendix to Chapter IV, p. 608.

II. NEW HAMPSHIRE.

The State for which we have the best evidence is New Hampshire. A careful study of taxation of timber lands in this State has been made by Mr. J. H. Foster, of the Forest Service, and a large amount of valuable material gathered. This material makes it possible to present a fair idea of the actual burden of taxation borne by timber lands in New Hampshire.

For this purpose the State naturally divides itself into two parts. The southern part is the prevailing wood-lot section; in general, the lots are not of great size and they are situated in well-settled incorporated towns. In the north, although here, too, we find many wood lots, a large part of the forests is owned by lumber and paper companies, institutions, estates, and persons of large means. Much of this land is located in unincorporated places.

The average tax rate for all the incorporated towns of the State in 1907 was 1.99 per cent.[a] For each county the average rate for the incorporated towns is shown in the following table:[b]

New Hampshire tax rates, 1907.

	Per cent.
Average for the State	1.99
Rockingham County	2.11
Strafford County	1.95
Belknap County	2.29
Carroll County	1.95
Merrimack County	2.02
Hillsboro County	1.87
Cheshire County	1.77
Sullivan County	2.09
Grafton County	2.23
Coos County	2.14

The prevailing rates in the several towns lie between 1.5 and 2 per cent. Of the 235 towns in the State, 113, or 48 per cent, have rates ranging from 1.51 to 2; 45 towns, or 19 per cent, have rates from 1 to 1.5; and 54 towns, or 23 per cent, have rates from 2.01 to 2.5; 21 towns, or 9 per cent, have rates above 2.5. The lowest rate in any town is 0.7, and only one other town has a rate below 1 per cent. The highest rate is 3.28, and only one other town has a rate above 3 per cent. The rate in the unincorporated places was 0.4 in 1907. These places have a very low rate on account of not having to pay town taxes.

The valuation of timber lands is made by local assessors in the incorporated towns and by the state board of equalization, with the assistance and advice of the county commissioners in the unincorporated places. Throughout the State timber lands are assessed far below their true value. From several hundred examples investigated, the following cases are given. These are cases in which the true values were ascertained with some accuracy.

An analysis of these figures gives a fair idea of the prevailing undervaluation of timber lands throughout the State. There are 56 examples in all. The average ratio of assessed to true value is 37.7 per cent. The closest approach to true value was made in the case where the forest was assessed at 86.6 per cent of its estimated true value. The lowest assessed valuation is 6 per cent. Of the 56 cases only 16 were assessed above 50 per cent of their true value and 21 cases were assessed below 25 per cent. In round numbers, more than two-thirds of these 56 forest properties were assessed at not more than one-half of their true value; three-eighths of the properties were assessed at less than one-fourth of their true value; and the average assessment for all 56 cases was only a little more than one-third of the true value.

The assessment varies somewhat with the region. It is highest in the wild lands of the unorganized parts of the State and in the southern wood-lot region. Of the cases in organized towns, about three-fourths were assessed at not more than one-half their true value, nearly half at less than one-fourth their true value, while the average assessment for all cases was only a little over one-third of the true value. An analysis of the examples according to region is given in the table below.

Percentage of assessed to true value, 1908.

Region.	Number of cases.	Average.	Highest.	Lowest.	Cases above 50 per cent.	Cases below 25 per cent.
Central wood lot	9	38.3	78	6	4	4
Southern wood lot	18	48	82	23	8	2
Wild lands in towns of South	4	28	47	17	0	2
Wild lands in towns of North	16	21.8	87	10	1	12
Wild lands in unorganized places	9	46	76	8	3	1
All cases in towns	47	36.2	87	6	13	20
Total	56	37.7	87	6	16	21

Extending this investigation, by taking in a number of examples where the true value can not be accurately determined and yet may be roughly estimated, produces results which agree substantially with the above. An investigation of something over 100 examples of wood lots in southern New Hampshire, estimating the true values roughly but very conservatively, shows that in fully three-fourths of the cases the assessed valuation is not greater than half the true value. In one-third of the cases the assessed value is less than one-fourth of the true value. There are a few extreme cases, both of high and of low valuations, but only three or four cases where the valuation appears to exceed the true value. There are a good many more cases where the property is ridiculously undervalued.

A similar investigation of a number of examples of wild lands in towns of northern New Hampshire shows a still lower basis of assessment. Hardly any cases appear where the assessment is more than half the true value. About half the examples were assessed at less than one-fourth the true value, the other half being assessed between one-fourth and one-half of the true value. A large number of cases appear where the assessment is only 10 per cent of the true value or even less. These results agree with the figures above based on cases where the true values were more accurately determined.

Having before us the facts regarding the tax rate and the ratio of assessed to true value, we are in a position to determine the actual burden of taxation on the forests of the State. The average tax rate of the towns in 1907 was 1.99 per cent. The average ratio of assessed to true value in the examples from towns was 36.2 per cent. Combining these figures would show an average tax of 0.72 per cent of the true value, or a little less than three-fourths of 1 per cent.

Again, 48 per cent of the towns have tax rates from 1.5 and 2, and another 19 per cent have rates from 1 to 1.5. Also, three-fourths of the cases of taxation in organized towns showed assessed valuations of not more than half the true value. These figures furnish a fair presumption that a large majority of forest properties are taxed at something less than 1 per cent of their true value.

A more satisfactory way of approaching this question is by an analysis of all the individual examples where it is possible to combine the tax rate and the ratio of assessed to true value. From about 150 such examples the following results are obtained. These results are in some cases based on fairly accurate knowledge of true values; the majority are based on more or less rough estimates of true value.

Less than one-fifth of the cases show a tax rate exceeding 1 per cent of the true value. The other four-fifths may be divided roughly into three equal groups. About one-fourth of the cases show rates from one-half of 1 per cent to 1 per cent; another one-fourth shows rates from one-fourth to one-half of 1 per cent; while one-fourth again shows rates below one-fourth of 1 per cent. In slightly more than half the examples the taxes do not exceed one-half of 1 per cent of the true value. These examples also show the relatively lower burden of taxation in the northern part of the State, where in nearly three-fourths of the cases the taxes are not over one-half of 1 per cent of the true value.

In the unincorporated parts of the State timber lands are taxed very leniently. With a tax rate of only four-tenths of 1 per cent, it hardly requires further evidence to show that the taxes are not heavy, even though the property were assessed at its full value, which is rarely, if ever, the case. The ratio of assessed to true value is, indeed, relatively high in the unorganized places.[a] The nine examples given showed an average ratio of 46 per cent. This would give an average tax of a little less than one-fifth of 1 per cent of the true value. Only a few examples showing the true value are available. Of these, the large majority pay taxes which are less than one-fourth of 1 per cent of the estimated true value of the property.

Thus far the attempt has been made to present the general situation in New Hampshire with regard to the burden of the general property tax on forest lands. Extreme and peculiar cases have not been discussed; we have described rather the condition of the general run of ordinary cases. Needless to say, there are plenty of cases that are peculiar in one way or another, and a glance at a few individual examples, taken more or less at random, may bring out a number of important and interesting side lights on this subject.

Several examples show a decidedly small burden of taxation. One tract of 200 acres in the mountains of southern New Hampshire covered with mature spruce has been assessed for years at $1,000. Recently the tract was sold for $5,000 and ten days later for $8,000.

In a certain town a farmer owns a number of lots in different parts of the town, worth altogether about $40,000. Outside the farm on which he lives, he is assessed for only $1,200. Apparently the assessors know very little about his valuable wood lots.

A certain old farm of 209 acres in southern New Hampshire has been assessed for the last twenty years at $500. In 1906 the assessors decided that this was too low and raised the valuation to $1,000. Since then the farm has been sold for $13,000 and it is now being assessed for $10,000.

Another wood lot was assessed at $250. Some one complained that this lot was not being taxed enough and the assessment was raised to $1,200. Soon after a lumberman paid $6,000 for the timber alone, leaving the farm still worth as much as $1,200.

A valuable piece of timber land about which the assessors apparently had little information was sold to a lumber company for $15,000. Its assessed valuation at the time was $500. Even after the sale the assessed value was raised only to $1,100.

Some equally interesting examples show what is undoubtedly excessive taxation. A lot of 1,628 acres in northern New Hampshire was assessed in 1906 at $3,300 or about $2 per acre. Next year the valuation was raised to $3.42 per acre, and in 1908 was increased to $50,000, or an average of $30.32 per acre. The paper company which owns this tract has complained against this assessment, and it is said that they are willing to sell the tract for $10,000, or one-fifth its assessed valuation.

Four lots in a town of northern New Hampshire were assessed for a number of years at $700 each. The owner tried to sell the lots for this price, but was unable to find a buyer. They were finally sold for $500. As the tax rate in this town was 2.25 per cent, this means a decidedly heavy burden of taxation.

A water company in a town of southern New Hampshire is assessed $100,000 on 70 acres of land and improvements. The improvements are estimated as worth $60,000, leaving an assessed valuation of $40,000 on 70 acres of land, or an average valuation of $571.43 per acre. The tax rate in this town in 1907 was 1.55 per cent.

A wood lot in northern New Hampshire, containing 250 acres, was bought at auction for $1,400. Soon after the assessed valuation, which had been very low, was increased to $1,800. Part of the timber was then cut off and sold, but the valuation was further increased to $2,100. This property is probably not worth its assessed valuation. As the tax rate in the town is 2.95 per cent, this means a decidedly heavy tax.

---

[a] See table above, p. 594.

A wood lot in southern New Hampshire was purchased for $1,000. It had previously been assessed at $400, but this valuation was immediately raised to $3,000 or three times the purchase price. The tax rate in this town in 1907 was 1.85 per cent. Assuming that the purchase price represented the real value of the lot, this lot is taxed over 5½ per cent of its value every year. In this particular case, the owner made no complaint, for the reason that he believed this excessive taxation was counterbalanced by undervaluation on some of his other lots.

The cases given above have illustrated not only the possibility of very heavy and very light burdens of taxation, but have also served to show the arbitrary and uncertain character of the prevailing methods of assessment. They show how eagerly the sale of a piece of property is seized upon by the assessors as evidence showing its value, which apparently had been only guessed at before. It may be worth while here to refer to some other examples showing the general character of assessment.

Two wood lots in southern New Hampshire were carefully examined and compared with each other. The lots were of the same general character, about equally distant from town, and apparently of about the same value; each was recorded in the tax books as containing 25 acres. One was assessed, however, for $800 and the other for $1,500.

Another example showing unequal assessment is that of a wood lot of 100 acres and an adjoining farm and wood lot in a town of southern New Hampshire. The 100-acre wood lot is probably somewhat more valuable than the adjoining farm and wood lot; yet the former is assessed at $500 and the latter at $3,500.

In some places the assessors purposely undervalue timber lands for the reason that the forests in the neighborhood of summer resorts add to the attractiveness of the region and therefore to the profits of the inhabitants. It is wished to encourage such natural advantages by a low burden of taxation. The evidence shows that in some towns such forest tracts are practically untaxed through the force of public opinion. For example, two lots in such a town were assessed at $500, while their true value is shown by their later sale for $5,800.

Reference has been made to the eagerness with which sales are seized upon by the assessors as giving evidence of the value of timber land. Two other examples of this may be of interest. A timber tract in southern New Hampshire was sold in 1905 for $12,000. Up to that time it had been assessed at $900. After the sale this valuation was raised to $4,000, still, however, only one-third of the purchase price. A wood lot which was sold in 1907 for $7,000 had been assessed up to that time at $500. After the sale the valuation was raised to $3,500. The owner complains that he is overtaxed in spite of the fact that his assessed valuation is only one-half the price paid for the land.

Almost every example of successive assessments for a number of years shows the striking tendency toward increased valuations during recent years. We may cite a few such cases by way of illustration.

A tract of 100 acres in Cheshire County, of which about 80 acres are covered with a good growth of pine, was assessed in 1897 at $1,000, in 1899 at $1,300, in 1900 at $1,600, in 1901 at $2,000, in 1902 at $2,300, in 1904 at $3,250, in 1905 at $4,500, in 1906 at $5,000,[a] and finally in 1908 at $7,000.

One of the most striking cases of increased valuation occurred in one of the upper Connecticut Valley towns. This town raised its valuation on timber lands $90,000 in 1908. Expert estimators were employed to value the timber. The valuations were considered decidedly lenient, yet the assessment of one company was raised from $3,050 to $16,000, that of another company from $5,000 to $50,000, while one small wood lot was raised from $250 to $4,000.

In a certain town of northern New Hampshire the total "nonresident valuations" of timber lands have been raised since 1892, as is shown by the following figures:

1892	$37,018
1902	43,980
1904	88,572
1905	112,368
1908	267,500

---

[a] New Hampshire Forestry Commission, Report 1905-6, p. 206.

A tract of 10,000 acres in northern New Hampshire was valued in 1890 at $6,000, in 1895 at $10,000, in 1900 at $20,000, in 1905 at $30,000, and in 1908 at $60,000, a tenfold increase in eighteen years.

A certain tract in the unincorporated part of the State was assessed in 1902 at $200,000 and four years later for $325,000. In 1890 the valuation was only $25,000.

A certain city in southern New Hampshire undertook to assess its timber lands carefully after a thorough valuation by a board of experts. Having obtained as nearly as possible the true value of each lot, its assessed value was placed on the books at about 60 or 70 per cent of the estimated true value. The result of this method of assessment was to enormously increase the assessed valuations. Out of 24 examples taken from the tax books of this town only three cases appear where the increase was less than 100 per cent. In these cases the valuations were increased, respectively, 40 per cent, 66 per cent, and 66 per cent. In five cases the valuation was doubled, in five cases trebled, and in the other cases increased still more. In one case the assessment was eight times what it was before. This example is good evidence of the prevailing undervaluation of timber lands and of the result that would follow strict assessment according to true value, and it should be remembered that in this case the assessed valuation was purposely put at about two-thirds of the estimated true value.

In conclusion, this investigation of conditions in New Hampshire serves to demonstrate (1) that the assessment of timber lands is more or less arbitrary and uncertain, often being a matter of mere guesswork; (2) as a result there are many individual cases of ridiculously low valuation and some cases of excessive valuation; (3) that in the general run of cases the burden of taxation is decidedly moderate; (4) and, finally, that there is a tendency toward higher assessment and heavier taxes. These conclusions receive further support from the report of the New Hampshire Tax Commission of 1908.[a]

III. OTHER NEW ENGLAND STATES.

It is unfortunate that such extensive evidence as exists in the case of New Hampshire is not available from other States. It is hoped that as this study progresses similar material may be collected from at least all of the other important timber-producing States. For the present we must be content to draw what conclusions we can from the testimony that is available from other parts of the country.

Considerable miscellaneous evidence seems to warrant the conclusion that the general situation in Maine is substantially similar to that of New Hampshire. Here also we find a large territory which is not incorporated and has no town taxes to pay. The most important facts regarding the taxation of these lands are shown in the following quotation:[b]

"A late estimate places the total amount of wild land in Maine at 18,000 square miles, three-fourths of which is not incorporated. The unincorporated townships are in Aroostook, Franklin, Hancock, Penobscot, Piscataquis, Oxford, Somerset, and Washington counties, the value of which is fixed once every two years by the state assessors, and forms the valuation on which the state and county taxes are based. These unincorporated lands are subject to the same rate of state and county taxes as property located in cities and towns. In addition, the owners of wild land pay for the building and maintenance of all highways. In 1870 the total valuation of the unincorporated townships was fixed at $5,156,356, an average of 55 cents an acre. In 1880 the value was increased to $7,984,060, an average of 92 cents an acre. In 1890 the valuation was raised to $19,146,458, or by more than 100 per cent, the average value of each acre being $2.07. The state board of assessors was created in 1901, its first assessment made in 1902, since which time the unincorporated townships have been assessed $11,660,070, or 51 per cent more than in 1890. During the same period other property in the State has increased in value only 13 per cent."

This increase has continued till at present the wild lands are valued by the state assessors at $37,559,000. The State and counties derive from them an annual income of about $186,000.

The tax rate in the unincorporated places is made up of a uniform state rate of 3 mills, and a county rate varying from 1 to 5 mills and averaging 2 mills. The total tax rate is therefore in the neighborhood of 5 mills, or one-half of 1 per cent. This tax, combined with the evidently low valuation, means a very light burden of taxation. There has of late been considerable popular complaint against the relatively small taxes paid by the large lumber and paper companies and other wealthy owners of wild lands in the unincorporated parts of the State. A good deal of agitation in favor of higher taxes has resulted. At the last session of the legislature a commission was appointed to investigate the general subject of taxation, having this idea particularly in view. A plank in the Democratic platform in the State campaign last fall demanded higher taxation of wild lands. A most decided tendency to increase the valuation of wild lands is shown in the figures given above. It should be remembered, however, that there has been a great increase in actual values during recent years.

---

[a] N. H. Tax Commission Report, 1908, pp. 175-199.

[b] American Lumberman, Sept. 22, 1906, p. 26.

In the incorporated towns of the State the average tax rate is about 21 mills,[a] or 2.1 per cent. This is slightly higher than in New Hampshire. In the absence of statistical data as to the relation between assessed valuation and true value, we can not determine definitely the burden of taxation. There seems, however, to be no widespread complaint of excessive taxation.

The data in the other New England States are not sufficient to warrant any positive conclusions as to the burden of taxation on timber lands. Occasional cases of excessive taxation are on record, as well as occasional cases where the owner admits his taxation is very light. There seems to be no evidence showing that timber lands are generally subjected to an excessive burden of taxation or that any widespread dissatisfaction exists. The following quotation is of interest in this connection:[b]

"In general, the assessment of white-pine lots is moderate, or even low, in comparison with the sale value. The rate of taxation varies exceedingly, but generally falls between $1.50 and $2 per hundred dollars valuation. The rate in some towns is as low as $1.20, but occasionally it reaches $3. Local taxation is controlled by the town, and the assessment and the rate depend upon the condition of the town's finances. The building of a new bridge or a schoolhouse often causes the tax rate to be raised considerably for a time. The valuation of the property is made by a local board of assessors, which frequently includes the valuation of a pine-wood lot in that of the whole farm of which it is a part. No exact rule exists with regard to the age at which a growing stand of pine shall begin to be taxed. Sometimes the assessors double or treble the valuation of a pine lot within a short period of years. Property is usually supposed to be revalued at stated intervals of eight or ten years, but this is not often regularly done.

"A high valuation or a heavy tax rate forces the owner to cut his pine lot at once. Towns where high taxes are levied on woodland are usually devoid of timber. Local assessors are beginning to learn, however, that a reasonable valuation and a moderate tax on pine lots for a considerable number of years mean a greater total income to the town than one heavy tax which compels the owner to cut his wood lot.

"Upon the whole, there is no great injustice practiced under the present method of taxation. Its greatest fault lies in the lack of a stable, regular system by which the valuation shall be fairly made and regularly increased according to the age and value of the stand, so that the owner may know whether he can afford to keep his stand and allow it to grow another ten years, when that period means a large proportionate increase in its yield."

The subject of forest taxation was investigated by a legislative committee in Massachusetts in 1905, but their report gives no data as to the actual burden of taxation on timber lands.[c]

IV. LETTERS FROM LOCAL ASSESSORS AND OTHER OFFICERS.

Some important material has been obtained from letters of local tax assessors, town and county officers, and others. These letters are in reply to a schedule of questions sent out by the Forest Service. Information has thus been received from 175 counties of Alabama, California, Iowa, Louisiana, Maryland, Michigan, Minnesota, New York, North Carolina, Pennsylvania, and

---

[a] American Lumberman, Sept. 22, 1906, p. 26.

[b] Forest Service Bulletin, No. 63, p. 31.

[c] Report of Committee of 1905 to Consider the Laws Relative to the Taxation of Forest Lands. Massachusetts State Forest Service, Bulletin No. 3.

Washington. With reference to the particular subject of this chapter, these statements show for each county (1) the lowest, and (2) the highest, assessed valuations of timber lands; (3) the assessed valuation of what are considered representative tracts of timber land; (4) the estimated true value of representative tracts; (5) the total tax rate (state, county, town, etc.); (6) the fixed ratio of assessed valuation to true value, and (7) the ratio of the tax to the true value of the land. These figures, which are given in full in Table B following, speak for themselves, and discussion is hardly necessary. So far as they go, they show the wide range in the valuation of timber lands which we should naturally expect; they show that timber lands are valued for taxation far below their true value; and they show the well-nigh universal custom of assessing property considerably below its true value, generally at some fixed ratio.

The general conclusions to be drawn from these figures will appear more clearly from Table A below, where the results are summarized by States. For example, in 21 counties of Alabama representative tracts of timber land are assessed at from $1 to $20 per acre, the true values ranging from $1.25 to $25. The tax rate varies in the several counties from 1.15 per cent to 1.50 per cent. The ratio of assessed to true value ranges from 25 per cent to 75 per cent, though for nearly all the counties it is between 50 and 60 per cent, the average for all counties being 58 per cent. The ratio of tax to true value averages 0.79 per cent and is less than 1 per cent in every county. The table shows the corresponding facts for each of the other States. These figures seem to show heavy taxation in California, Michigan, and Washington, rather heavy in Iowa, Louisiana, Minnesota, and Pennsylvania, and a light burden in Alabama, Maryland, New York, and North Carolina.

TABLE A.

State.	Number of counties.	Assessed value of representative tracts.	True value of representative tracts.	Tax rate.	
				Range.	Average.
				Per cent.	*Per cent.*
Alabama	21	$1.00-$20.00	$1.25-$25.00	1.15-1.50	1.35
California	19	2.00-100.00	5.00-200.00	1.00-3.55	1.89

[a] Valuation of stumpage per m. [b] Plus land at $1.25. [c] Plus land at $2.50. [d] Per m.

V. MISCELLANEOUS EVIDENCE.

Some valuable evidence regarding the taxation of timber lands in Illinois has been prepared by a member of the Forest Service. Nine counties were studied, from which we obtain the following information: The average tax rates of the different counties range from 4 to 6 per cent, the average for all nine counties being 4.75 per cent. The practice of assessors in these counties is to value property very low. The assessed valuations run from one-fifth to one-eighth of the true value, or even less. For example, in one county improved lands were assessed on the average at $12 per acre and unimproved lands at $1.70. The market value of land in this county is estimated at from $40 to $60 per acre for improved lands, and from $5 to $15 for unimproved lands. In another county where improved lands were assessed at an average of $5.48 per acre, the true value was estimated at from $25 to $35. In another county the average assessed value of improved lands was $7.15, while the true value was estimated at about $35. The average assessed valuation of improved and unimproved land and the average tax rate for each county are shown in the following table:

Illinois, nine counties.

County.	Average assessed valuation of land.		Average tax-rate percentage.
	Improved.	Unimproved.	
Alexander	$12.01	$1.71	5
Clinton	5.48	1.49	4
Fayette	7.15	3.49	4
Gallatin	7.10	1.72	5.75
Jackson	31.15	7.46	4
Johnson	5.50	1.55	4
Pope	6.34	2.64	6
Saline	5.41	1.20	6
Union	6.24	1.96	4

Combining these tax rates with the ratios of assessed valuation to true value, ranging from one-fifth to one-eighth, it would appear that lands are taxed on the whole somewhat less than 1 per cent of their true value, the general run being perhaps two-thirds of 1 per cent up to 1 per cent. These, of course, are only averages for the several counties. Extreme cases must undoubtedly be present, involving exceptionally high and exceptionally low taxation. It seems reasonable to conclude, however, that the majority of the lands in these counties are certainly not taxed more than 1 per cent of the true value.

The following quotation is of interest as showing the condition in Kentucky:[a] "The present valuation and rate of taxation on forest property seems fair and just and should remain as it is, as far as possible. When a rise in the valuation of other than forest property becomes necessary because of the greater development of the resources of the region, the valuation of forest property should be increased with great caution in order that the forest lands may be held to advantage for the production of future timber crops.

"In view of these facts, it is recommended that taxation of forest lands in this region be kept as nearly on its present basis as possible. If a readjustment of valuation should become necessary, care should be taken not to impose taxes that will prevent the profitable holding of forest lands by the private citizen for the production of timber."

A great deal of discussion of the taxation of timber lands has recently appeared in the forestry journals, the lumber trade journals, the publications of the United States Forest Service and of the several state foresters, and elsewhere. From these writings a few interesting examples of timber-land taxation may be culled. These sources are undoubtedly reliable, but naturally the cases given are mostly those of excessive taxation. A few cases may be worth while as showing, not the prevailing situation, but rather the extremes of excessive taxation found here and there. For example, "the forest commissioner of Pennsylvania reports that on one of the few pieces of virgin forest still standing in the State, containing a little less than 1,000 acres, the annual tax is $2.83 per acre. If the whole tract averages 20,000 feet per acre of white pine worth $10 a thousand on the stump—both estimates are high—the tax is 1.4 per cent of the value. The same authority * * * states that denuded lands are commonly assessed from 50 cents to $1.25 per acre, and that the usual levies amount to 25 to 30 mills. This means a yearly tax of 1¼ to 3¾ cents per acre. * * * The state forest reserve commission has bought at tax sales over 23,000 acres of such lands for the accrued taxes and costs. * * * The commissioner mentions one case where several parcels containing over 7,000 acres were bought in for a fraction over 8 cents per acre."[b]

It is stated that in Wisconsin the taxes on forest lands have been for years from 3 cents to 40 cents an acre without reference to changes in its condition or value, although more than one-third of the area of the State consists of cut-over lands too poor to be farmed and which may be bought for 25 cents to 50 cents per acre.[c]

"In North Carolina conditions are not much different. The common levy is 1 per cent on a 60 per cent valuation, or 6 mills on the estimated value. Where this value is justly assessed there can be no reasonable complaint, but there is much guessing, and in one county it is reported that land partly lumbered, or cut over as the forester advises, is taxed 25 per cent higher than virgin forest, on the ground that it is improved land. In other words, a penalty is imposed on conservative lumbering!"[d]

According to one of the Forest Service bulletins, cut-over lands in western Washington, which are valuable for nothing except the production of timber, are assessed at from $1 to $5 per acre, with a tax rate of from 15 to 30 mills on the dollar. These lands are estimated by the same authority as actually worth not more than $1 per acre. Large tracts of this land have been sold for 40 cents an acre.[e]

An interesting example of increased assessment comes from Oregon. One owner paid taxes amounting to $496.69 in 1907 and this year was called upon to pay $1,855.32, an increase of 274 per cent. Another tract was taxed $528.50 in 1907 and $1,804.54 in 1908. In another instance a timber claim which the owner was willing to sell for $2,400 was assessed for $4,700.[f]

Besides a mass of other similar evidence from the sources quoted above, the writer is in possession of a great deal of testimony from letters which he is not at present at liberty to make public. This testimony is in general accord with the evidence presented, and has been drawn upon in forming the conclusions expressed in the text. In New Jersey, for example, it is stated that timber lands are not compelled to bear a heavy burden of taxation at the present time, although here and there individual cases of excessive taxes are to be found. In general, timber lands are assessed far below their true value. In south New Jersey it is said that land bearing young pine is commonly taxed on a value not exceeding $1 per acre and that hard-wood forests in the northern part of the State, when newly cut over, are often assessed no higher than this. Similar testimony is at hand from Georgia, to the effect that the very low assessment of forest lands has thus far prevented excessive taxation on any large scale.

CHAPTER IV.

THE EFFECTS OF TAXATION ON THE FORESTS OF THE UNITED STATES.

Having shown, in a general way, what the actual burden of taxation on timber lands is at present, we must next inquire what effects taxation has had upon the forests of the country. It is commonly charged that taxation is responsible, (1) for a great deal of premature cutting of timber which would otherwise be left to grow to larger size; (2) for wasteful and destructive methods of cutting, commonly called "skinning;" (3) for the failure to hold lands once cut over for a second crop; and (4) for the general absence of the practice of forestry in America. It is important to know how far these charges are sustained by facts.

To a considerable extent the answer to this question may be inferred from the foregoing conclusions as to the burden of the general property tax on forests. There can be no doubt that in many of the cases where taxation has been excessive it has hastened the cutting of timber and led to wasteful skinning of the land, often destroying the chance of a valuable second growth, and sometimes leading to the abandonment of the land for delinquent taxes. On the other hand, in all those cases where the tax burden has been very small, taxation can obviously have had little influence on the management of the property.

The evidence on this question is from much the same sources as the evidence upon the burden of taxation discussed in Chapter III. This evidence, so far as it goes, shows that in some States, where taxation of timber lands and waste lands has been excessive, the taxation has had some influence in causing premature and wasteful cutting and in preventing the holding of cut-over lands for a second crop. Such evidence comes mainly from the States of Michigan, Wisconsin, Minnesota, Washington, and California. These are the States where we have seen some tendency toward excessive taxation of timber lands. The effects of taxation are more noticeable in preventing the reforesting of cut-over lands than in altering the management of mature or growing timber. These five are among the most important lumber-producing States of the country. They furnished one-fourth of the total cut in 1907. In them there is some evidence showing that considerable cut-over land has been abandoned because of the heavy taxation. This matter of abandoned lands is discussed more fully below.

On the other hand, there is evidence from a great many States tending to show that taxation has had no appreciable effect on the forests. These are States where the burden of taxation is so very light that it is seldom considered by timber owners and lumbermen.

In the general run of ordinary cases, as has been shown, the present burden of taxation can not be considered excessive. And in the general run of cases also there is little evidence to show that forests have been affected seriously by taxation. Indeed there is much positive evidence to the contrary. Among other sources, we have letters from nearly five hundred of the leading lumbermen of all parts of the country, written in reply to a schedule of inquiry sent out by the Forest Service. In answer to a question as to the influence of taxation on their lumbering operations, only 125 admit that it has had any appreciable effect. This includes a number of doubtful ones. The number that clearly testify to some undoubted influence on the part of taxation probably does not exceed 100. Of the replies, 234 state absolutely that taxation has had no influence, or very little. This testimony is discussed and the replies tabulated by States in the appendix to this chapter, from which it will be seen that the chief complaint of serious results of taxation comes from a small number of States, to some of which attention has already been called.[a] As said above, however, these States include some of the most important timber-producing States in the country.

It appears that in the general run of ordinary cases and in most parts of the country, at any rate outside of the five States named above, taxation has not had any great influence in causing the cutting of timber, and not very much influence in preventing reforesting. That the American forests have been cut off at a tremendous rate of late years, that the methods of cutting have often been wasteful and destructive of future growth, and that there is little tendency on the part of lumbermen to reforest cut-over lands are facts which need no demonstration. But that taxation has generally been an important influence in bringing about these results is an inference apparently not warranted by the facts. This is a phase of the problem which has been greatly exaggerated. The explanation probably lies in the fact that most of the discussion thus far has been on the part of those who were complaining against some particular cases of evil results from excessive taxation. That such cases undoubtedly exist in considerable number has already been shown. That they do not represent the prevailing situation has also been shown. The recent heavy and wasteful cutting of our forests has been due to various economic influences, among which taxation has played a comparatively small rôle.

A good deal of cut-over land has been abandoned for taxes in certain parts of the country, particularly in the States in the region of the Great Lakes and on the Pacific coast. California probably has about a million acres of such delinquent-tax lands. Michigan also has about a million acres. Wisconsin has a large area. In some cases this has been due, in part at least, to excessive taxation. For example, in western Washington cut-over lands are assessed at from $1 to $5 per acre, although according to the estimate of a Forest Service expert the land is not worth more than $1 per acre, and large tracts have actually been sold for 40 cents an acre.[b] But while this state of affairs exists in some States, and is in some cases due to excessive taxation, still throughout the country as a whole there is very little land abandoned for taxes, and in the great majority of the States the matter of abandoned lands is negligible.

---

[a] See Appendix to Chapter IV, p. 608.

[b] Forest Service Bulletin No. 33, pp. 36, 37, 45.

As evidence on this point, it is significant that out of nearly five hundred letters from lumbermen all over the country only eight stated that taxation had led them to abandon their lands.[a] Further evidence on this subject comes from letters received from local tax assessors and others in 177 counties of Alabama, California, Iowa, Louisiana, Maryland, Michigan, Minnesota, New York, North Carolina, Pennsylvania, and Washington. Out of these 177 counties only 25 report any appreciable amount of abandoned lands; and, so far as these replies go, they seem to show that in the great majority of counties practically no land is being sold or abandoned for taxes, and that in only a few counties is the question of delinquent tax lands a matter of any importance.[b]

Forestry is very little practiced in America to-day, but that this state of affairs has been due in any great measure to taxation is denied by the evidence. The lumbermen, as a rule, are not thinking much about forestry. There are other factors in the forestry problem of far greater weight than taxation, and the general practice of forestry will not be brought about by amendments to the tax laws. This conclusion also is supported by the great majority of the letters received from lumbermen all over the country. The majority either ignore the question altogether or state that a change in taxation would make no difference in the management of their lands. And of the others, very many admit only a problematical effect, or an effect in some cases. In answer to the specific question, whether reduced taxes would lead to planting or holding cut-over lands for second growth, the number of affirmative replies is still smaller.[c]

We conclude, then, that while in some cases, and in certain parts of the country, forests have been excessively taxed with more or less serious results, as a general rule taxation has not, up to the present time, been responsible for any widespread disastrous results on the forests of the country.

APPENDIX.

SOME EVIDENCE REGARDING THE EFFECTS OF TAXATION ON THE FORESTS OF THE UNITED STATES.

1. LETTERS FROM LUMBERMEN.

The following questions, among others, were sent to representative lumbermen all over the country by the Forest Service in the summer of 1908:

1. In what way, if any, have your lumbering operations been influenced by the rate of taxation applied to your holdings?

2. Would a reduced tax lead you to adopt different methods so as to preserve young growth or to leave seed trees in order to provide for a future crop, and for the protection of cut-over land from fire?

a. Would it lead you to plant such of your holdings as have been cut over when planting is necessary?

b. Would it influence you not to abandon cut-over lands? If so, what would the ratio between the present tax and the reduced tax have to be?

About 500 answers were received which give some valuable testimony as to the effects of taxation on the forests of the country. Incidentally they throw some light on the actual burden of taxation on timber lands. In some cases the replies are not very clear, and it has requiued the exercise of some judgment to tabulate them. The doubtful cases, however, are not numerous enough to affect the conclusions to be drawn from the answers.

---

[a] See above; also Appendix to Chapter IV, p. 609.

[b] The full replies to this question are given by States and discussed, together with some other evidence on the subject of abandoned tax lands, in the Appendix to Chapter IV, p. 611.

[c] The evidence is presented and discussed in the Appendix to Chapter IV, pp. 611.

The answers to the first question may be classified as follows:

Answers to question 1.

1. Number of letters received	484
2. No information on this question	117
3. No influence, or very little	234
4. Probable future influence	8
5. Some influence	125
a. Character not specified	1
b. Hastens cutting	117
c. Leads to abandoning land	8

The cases in which taxation is said to have exercised some influence include a number of rather vague replies. Probably the number that clearly testify to some real influence would not be over 100. These replies are significant as showing how little influence taxation has really had upon the management of forest properties.

The replies give additional information of interest when they are classified by States, as is done in the following table, though the number of cases in many individual States is too small to allow the drawing of any positive conclusions:

Answers to question 1, by States.

State.	1. Number of letters received.	2. No information.	3. No influence, or very little.	4. Probable future influence.	5. Some influence.

All others [a]	5	1	4	....	0	....	....	....
Total [b]	497	120	242	8	128	2	119	8

[a] Cases where the State was not indicated.

[b] The totals here exceed those in the summarized table above, for the reason that replies from companies operating in more than one State have been counted under each State.

The replies to questions 2, 2*a*, and 2*b* show the following results:

Answers to question 2.

1. Number of letters received	484
2. No information on this question	100
3. No, or doubtful	166
4. Yes, or probably, or in some cases	218

Answers to question 2a.

1. Number of letters received	484
2. No information on this question	173
3. No, or doubtful	182
4. Yes, or possibly, or would consider it	129

Answers to question 2b.

1. Number of letters received	484
2. No information on this question	184
3. No	123
4. Yes	177

Here also, as in tabulating the answers to the first question, a good many rather vague statements have been counted as affirmative replies. The number of clear and positive affirmatives would be considerably below the figures given above.

II. LAND ABANDONED ON ACCOUNT OF TAXES.

Some interesting evidence on the subject of delinquent-tax lands has been obtained from letters of local assessors, town and county officers, and others, received in reply to a schedule of questions sent out by the Forest Service. One of these questions was, "To what extent has cut-over land in your locality reverted to the county or State or been sold because of nonpayment of taxes?" Answers to the general schedule were received from 175 counties of Alabama, California, Iowa, Louisiana, Maryland, Michigan, Minnesota, New York, North Carolina, Pennsylvania, and Washington. In answer to the question about delinquent-tax lands, 73 counties report "none;" 37, "very little;" 2, "none lately;" 38 give no answer at all; and 25 report some abandoned lands together with some information as to their extent. The information contained in these last 25 replies is as follows:

In Alabama, one county reports one-fourth of 1 per cent, another 1 per cent, and the third, "some." In California, one county reports one-twentieth, and one, 23,638 acres. Four counties in Louisiana report, respectively, "some, but soon redeemed," 15 per cent, 360, and one-tenth. Six counties in Michigan answer, respectively, 5 per cent, less than 1 per cent, 1,009, 10 per cent, 10 per cent, and 300. One county in Minnesota reports 300 acres. Two counties in New York report, respectively, 10 per cent, and 6 per cent. In North Carolina, one county reports 10 per cent and another 5 per cent. In Pennsylvania 5 counties report, respectively, "some," "great extent," "300 acres every two years," 1,000 acres, and "nearly all." The exact meaning of these replies is not always very clear.

These replies, so far as they go, seem to show that in the great majority of counties practically no land is being sold or abandoned on account of taxes, and that in only a few of the counties is the question of delinquent-tax lands a matter of any importance. The returns, summarized by States, are given in the following table:

Lands abandoned on account of taxes.

State.	Number of counties.	None.	Very little.	None lately.	No answer.	Some; extent specified.
Alabama	21	9	6	1	2	3
California	19	3	6	1	7	2
Iowa	20	15	1		4	
Louisiana	24	14	3		3	4
Maryland	1	1				
Michigan	18	7	2		3	6
Minnesota	18	3	3		11	1
New York	10	3	4		1	2
North Carolina	22	11	7		2	2
Pennsylvania	11	3	2		1	5
Washington	11	4	3		4	
Total	175	73	37	2	38	25

The following statement, taken from Forest Service Bulletin No. 33, page 37, gives some additional evidence. The reports were furnished by the assessors of some of the timbered counties of the State of Washington, and state the amount of cut-over land which has been abandoned:

Abandoned lands in Washington.—Chehalis County, 71 per cent; Clallam County, none nominally abandoned, much delinquent; Clarke County, none; Jefferson County, 20 per cent; King County, none; Pacific County, none at present, indications that large amount will be abandoned; Pierce County, information wanting; Skagit County, very little; Whatcom County, 20 per cent.

CHAPTER V.

THE REAL ECONOMIC PROBLEM OF FOREST TAXATION.

It does not follow from the conclusion reached in the last chapter that the problem of forest taxation is of no importance or of academic interest only. The problem is, in fact, of the utmost importance, and is moreover decidedly practical. But its practical bearing is on the future of our forests rather than on their past. The methods of handling the forests of the United States which have prevailed in the past can not continue much longer. This statement is supported by such an overwhelming mass of testimony on the part of the forestry experts that we may accept it without further discussion. On the same authority we accept the proposition that the preservation of our forests is a matter of urgent importance, and that disastrous consequences are bound to follow their destruction. The practice of forestry, then, must come some time, and its speedy coming is a thing greatly to be desired; and whenever we are ready to seriously undertake it, we will find our present methods of taxation a heavy handicap. It is then that taxation will appear as a vitally important element in the situation.

It can be shown theoretically that the general property tax, strictly enforced in accordance with the letter of the law, must inevitably lead to excessive taxation in all cases of invested wealth which is appreciating in value. Suppose a man invests $10,000 in a perpetual annuity at 5 per cent, yielding an annual income of $500. Suppose an annual property tax of 1 per cent is imposed. The tax will take $100, or 20 per cent of the income each year. Suppose now that another man, having $10,000, puts it in trust for fourteen years, after which time, the principal having doubled, he invests it in a perpetual annuity of $1,000 a year. Under the property tax he is taxed $100 the first year, but the second year, his capital having increased to $10,500, he pays a tax of $105. His tax increases each year till the fourteenth, after which it is $200 a year. The present value of all the taxes paid by the first man is $2,000, or 20 per cent of his capital. The present value of all the taxes paid by the second man is $3,428, or 34 per cent of his capital. That is, the man who does not use up his income, but invests it, is punished by an excessive tax.[a]

Now, the business of forestry is apt to be like the investment of the second man. The annual growth of the trees, instead of being taken each year as income, is left to increase the capital, till many years later when the timber is cut and the income begins to accrue. A property tax, strictly enforced, must inevitably place an excessive burden upon forests as compared with the ordinary investments yielding a regular annual income. It might easily take away from one-third to one-half of the entire net income, and very much more under certain conditions. This assumes, what the law clearly requires, that the forest be taxed each year on its true value, land and timber together.[b] Forestry should not be subjected to such an unjust burden.

It may be objected that as a matter of fact forests are not taxed on anywhere near their true value, and this practice should be recognized. But this does not relieve the situation much. Probably nothing more effectually discourages investment than uncertainty as to future costs. And whatever may be said of the present system of taxation, there can be no question of its arbitrariness and uncertainty. If to all the other risks of forestry we add uncertainty as to what the taxes are going to be, we can not blame investors for some hesitation in embarking on an enterprise which may have to pay taxes fifty years before the returns come in. And more than this; the investor can not safely base his calculations on the continuance of the present lenient administration of the property tax. As has been shown, the tendency to-day is toward a stricter enforcement of the law and a heavier burden of taxation.

There is a good deal of evidence from a variety of sources tending to show that in the few cases where forestry has already been seriously considered, the matter of taxation has been one of the most important items in the calculation and in many cases has been an insuperable obstacle.

The problem of forest taxation is, then, an important one, and a very practical one. It is safe to say that we can hardly hope to see the general practice of forestry by private owners until our methods of taxation are made more scientifically equitable and certain. The importance of this problem will necessarily increase as time goes on until it is properly solved. The subject, therefore, deserves the most careful and thorough investigation.

---

[a] For a discussion of the economic principle here involved, cf. Fisher, "The nature of capital and income," Chapter XIV; especially pp. 249-255.

[b] For a further discussion of this matter based on mathematical examples, see Appendix to Chapter V, p. 613.

APPENDIX.

MATHEMATICAL ILLUSTRATION OF THE POSSIBLE BURDEN ON FORESTRY OF THE GENERAL PROPERTY TAX.

This appendix presents mathematical examples illustrating the statement of the text that the general property tax, strictly enforced according to the letter of the law, might easily take away a very large part of the income of the business of forestry. In these examples, the figures for cost of planting and value of standing timber are taken from an example worked out by the New Hampshire forestry commission.[a] The figures are for white pine in the State of New Hampshire. In all cases the rate of interest is assumed as 5 per cent.[b] The figures are for 1 acre of land.

Table A gives the following facts for five-year periods from the twentieth year to the seventieth: (1) The cost of planting, with accrued interest to the several dates; (2) the value of the standing timber at the several dates; (3) the net income of the forests, which is the difference between the value of the trees and the cost of planting, with interest to date; (4) the present expectation value of the forest if cut, respectively, at the three years which give the largest value; (5) the amount of the taxes with accrued interest to date—the taxes on the land and trees are given separately, the trees being exempt from taxation for the first 20 years; (6) the ratio of the taxes to the net income, given as a percentage; (7) the net income less taxes; and (8) the expectation value based on net income after deducting taxes. The tax rate is assumed at 1 per cent. It is assumed that the land is taxed on its full value—that is, on its present expectation value as a forest. In this example the most profitable year for cutting is the fiftieth. If cut in that year the present expectation value is $10.36. We have assumed that the land is taxed on a valuation of $10.

Some interesting results are evident from this table. In the first place, the taxes exceed the net income yearly up to the fortieth year and after the seventieth year. In the fiftieth year the ratio of taxes to net income is the smallest, being 39 per cent, and this year is still the most profitable cutting year, although the net income less taxes would be slightly greater if it were cut in the fifty-fifth year. Of course, the most important purpose of this table is to show that taxation under the assumed conditions will take 39 per cent of the total net income.

In order to show that the burden of taxation will still be very heavy, even though the land be valued considerably below its expectation value, Table B is presented. The figures in this table are the same as in Table A, with the exception that the land is assessed at $5. This is the value assumed by the New Hampshire forestry commission in their examples. In this case the taxes in the fiftieth year amount to 29 per cent of the net income, still a very high tax, although the land is assessed at only half of its true expectation value.

In Table C the circumstances are altered by assuming that the forest grows up without any cost of planting. Here also the most profitable cutting year is the fiftieth. Assuming that the forest is cut in this year the expectation value is $18, and we assume that the land is taxed on that value. The result shows a tax in the fiftieth year of 31 per cent of the net income.

In all these examples we have assumed a tax rate of 1 per cent, which is, of course, very low as compared with present prevailing rates, which are generally somewhere in the neighborhood of 2 per cent. One per cent was taken as representing roughly the percentage of present taxes to the true value of property. Since the total tax varies directly with the rate it is a simple matter to alter the figures in any of these examples to correspond to any given tax rate. As a single illustration of this Table D is presented, showing the result of a tax rate of 2 per cent under the conditions given in Table A. Obviously the taxes, and also the percentage of taxes to net income, are exactly doubled. The best that the forest owner can do is to cut in the fiftieth year and hand over 78 per cent of his net income in the form of taxes.

These examples, of course, show nothing as to the burden of taxation which may be expected under any particular conditions. They do show, however, the very heavy burden which may easily result from the general property tax under ordinary conditions.

---

CHAPTER VI.

THE PRINCIPLES OF SCIENTIFIC FOREST TAXATION.

The foregoing discussion has shown the fundamental weakness of the present methods of taxing timber lands and the necessity of adopting some scientific system which will secure both equity and certainty. It is now necessary to inquire into the fundamental principles which must be the basis of any correct method of taxing timber lands.

We may assume, without much danger of controversy, that taxation should be based on income or earning power. The tax on income may be collected at the time the income accrues, or it may be in the form of an annual tax on the capital value of the income. If the rates of the income tax and the capital tax bear the proper relation to each other, those two ways of applying the tax produce identical results. For example, if the interest rate is 5 per cent, an income tax of 20 per cent is equivalent to an annual capital tax of 1 per cent, provided the business taxed is earning a regular annual income. In general the rate of the capital tax is equal to the rate of the income tax multiplied by the rate of interest.

In the case of forests, the tax based on income may be applied in either of two ways, (1) as a tax on the yield whenever any timber is cut, or (2) as an annual tax on the present capital value of the forest, based on all its expected future incomes and expenditures, what the foresters call "expectation value." To illustrate by a single example, suppose that a forest is so managed as to yield a net income of $150 sixty years from to-day, and again every sixty years thereafter, without any cost for planting. If interest is at 5 per cent, a simple calculation will show that the present expectation value of the forest is $8.47. Suppose it is desired to tax this forest at the rate of 20 per cent of its net income. This may be accomplished either by a tax of 20 per cent of the net yield whenever it occurs, or by an annual tax of 1 per cent of the expectation value. The first would mean a tax of $30 paid every sixty years when the timber was cut. The second would mean a tax of 8½ cents paid every year. The present value of these two taxes—that is, $30 paid sixty years from date and every sixty years thereafter, and 8½ cents paid every year, beginning at once—is exactly the same.

The above is an example of a forest managed to produce a sustained periodic yield; that is, the timber is cut at long intervals, the forest being renewed after each cutting so as to produce about the same yield after each rotation period forever. Forests may also be managed so as to produce a sustained annual yield. In this case, timber is cut annually, about the same amount each year, and the forest is maintained without deterioration forever. And finally, forests may not be managed according to any system of forestry, the yield being purely irregular.

Obviously the tax on yield when cut may be applied to any forest, whatever the system of management, or even where no systematic management is employed. This method simply takes a certain part of the yield whenever any timber is cut. On the other hand, the tax on expectation value is more complicated. It requires the calculation of present value based on all future expected incomes and expenses. And in the case of the forest with irregular yield it is impossible to apply this method at all, for there is no way of calculating the expectation value.[a]

A matter of the utmost importance in the case of the tax on expectation value is the rate of interest at which the calculation is made. That a good deal depends on what rate is selected may be realized from the single fact that if in the above example 4 per cent had been used instead of 5, the annual tax would have been 16 cents instead of 8¼ cents. A change of a single unit in the rate of interest may double or even treble the amount of the tax. Evidently the rate of interest is the crux of the whole theory of the tax on expectation value. This subject has never received the thorough investigation which its importance deserves. A short discussion is given in the appendix to this chapter. The following very brief suggestions are offered here.

Writers of the technical works on forestry are inclined to capitalize forest investments at very low rates of interest, 2½ or 3 per cent being usually adopted. The writer is convinced that these rates are too low, at least for American conditions. To mention only two reasons for this belief: In the first place, the risk of fire is so great that no insurance company will accept it. In the second place, forestry is peculiar in the long interval of time which must generally elapse before the investment begins to yield an income. It is a well-known psychological fact that such an income will be discounted at a higher rate of interest than those whose enjoyment is less remote.

Without mentioning other reasons for a high rate, the writer is convinced that, as compared with ordinary investments, forest investments must be capitalized at a relatively high rate of interest. Five per cent is certainly not too high. It is very probably too low. This question must be carefully considered in applying a tax on expectation value.

The selection of the rate of the forest tax, whether a tax on yield when cut or on expectation value, is simple theoretically. If it is desired to place the same relative burden on forests as on other kinds of wealth, the rate on expectation value should be the same as the actual rate of the general property tax on true value;[a] the rate on yield when cut is the quotient of the rate of the property tax divided by the rate of interest. If it is desired to offer special inducements to forestry by a lower burden of taxation, the above rates may be reduced in any desired degree.

---

[a] For a more extended discussion of the theory of forest taxation, with numerous mathematical examples, see Appendix to Chapter VI, p. 618.

In order to avoid uncertainty and arbitrary taxation, the rate of the forest tax should be determined by a state officer or board, the rate to apply in all parts of the State; or the State may merely establish a maximum rate, leaving to any town the liberty to levy a lower rate if desired.

It has been shown that in general the scientific principles of forest taxation may be applied either as a tax on yield when cut, or as a tax on the capital value of the forest. It now becomes necessary to weigh the relative merits of these two methods of taxation with particular reference to American conditions.

No sooner is the question raised than the answer forces itself upon us that the tax on expectation value is not capable of general application in the United States. This method depends on the general practice of forestry, whereas in America the practice of forestry is the rare exception outside of the public reserves. This method requires the existence of accurate yield tables for the various species of trees and for different parts of the country. Only the smallest beginning has yet been made toward the construction of such tables for America. This method can not be applied to forests producing an irregular yield. Yet nearly all the forests in the United States are of this class.

These considerations alone show the impossibility of applying the tax on expectation value in America at the present time and for a long time to come. On the other hand, there are some positive considerations in favor of the tax on yield which are of the greatest importance. In the first place, the tax on yield avoids the whole problem of the rate of interest, which has been shown to be at once the most important and the most difficult theoretical factor in the tax on expectation value. When a forest is taxed on its yield, the value of the yield and the value of the tax will bear the same relation to each other, no matter what the rate of interest, since both are necessarily discounted at the same rate. For example, if a forest yields $150 net income every sixty years and is taxed 20 per cent of the yield, or $30 every sixty years, the present value of the tax of $30 will always be one-fifth of the present value of the yield of $150, no matter what rate is used in discounting. The importance of this argument in favor of the tax on yield can hardly be exaggerated.

Again, the use of the tax on yield relieves us of the necessity of estimating the future prices of timber. All calculations of expectation value are rendered more or less untrustworthy by the great uncertainty as to future prices of timber. All the estimates on this subject must be a matter of more or less skillful guesswork. The objection to a tax based on such calculations is obvious. On the other hand, future prices of timber are a matter of indifference as regards the principles of the tax on yield. Since the tax is a certain part of the yield, changes in price affect both the yield and the tax in the same way. Here also is a most weighty argument in favor of the tax on yield.

---

[a] For example, if the rate of the general property tax is 2 per cent, and property is usually assessed at a fixed ratio of 50 per cent of its true value, the rate of the tax on true value is 1 per cent.

Similarly, by basing the tax on yield, we eliminate the element of risk from the tax problem. The danger of loss by fire, etc., is so great that forestry investments are at best decidedly uncertain. This risk, as is shown above, should be taken into account in determining the rate of interest. But no one can estimate the degree of risk with any approach to accuracy, and no allowance in the rate of interest can prevent serious injustice being done in individual cases. An owner may have been paying taxes on his forest for fifty years, only to see the yield at last wiped out by a destructive fire. Moreover, such a system would act as a deterrent influence against forestry investments. When the annual taxes to be paid are a sure thing, while the yield to be obtained after fifty years is very uncertain, we can not blame the investor for hesitating. All this is avoided by the tax on yield. Forest investments will still be subject to risk, but the risk will not be complicated by taxation. Taxes are paid on the yield, and if the yield is destroyed by fire the taxes are thereby automatically remitted.

Another argument, though of less importance, is worthy of mention here. In certain cases the tax on expectation value might lead to premature cutting. If an owner became financially embarrassed, so that the payment of his annual tax became a matter of difficulty, he might be led to cut immature timber to get money to pay his taxes. The tax on yield would not have this influence.

We conclude, therefore, that the superiority of the tax based on yield when cut is demonstrated beyond question. We may therefore dismiss the tax on expectation value, and confine the discussion of practical applications and administrative problems to the tax based on yield when cut.

APPENDIX.

THE THEORY OF FOREST TAXATION.

I. THE THEORY OF FORESTRY AND FOREST TAXATION.

Assuming that taxation should be based on income or earning power, any given tax on income-producing wealth may be levied either as a tax on the net income whenever it accrues, or as an annual tax on the capital value of all the expected future net incomes.

In order to have a sound theoretical basis for the study of forest taxation, it will be necessary to inquire into the economic character of the business of forestry. Assuming that some regular system of forest management is in operation, the receipts and expenditures of a forest occur at different times, according to the way in which the forest is managed. In order to express the problem in mathematical terms, the following notation is used:[a]

Let p = the rate of interest.
Let r = the number of years in the rotation period; i. e., the number of years between successive major cuttings.
Let Y_r = the value less cost of harvesting of each final or major yield, realized every r years.
Let T_a, T_b . . . T_q = the value less cost of harvesting of the intermediate yields from thinnings, etc., occuring in the years a, b, . . . q. Each of these thinnings occurs during every rotation, that is, every r years. Thus the first thinning T_a occurs after a years, again after $a + r$ years, again after $a + 2r$ years, etc.
Let m = the annual value of any annually recurring incidental revenue, as, for example, grazing fees, rent of the forest for hunting, etc.

---

[a] Cf. Schlich, Manual of Forestry, Vol. III, third edition, pp. 122-126; Fernow, Economics of Forestry, pp. 215-216; etc.

Let M = the capitalized value of the annual incidental revenue; that is, $M = \frac{m}{.0p}$.

The quantity *m* (or M) may generally be disregarded, or may be assumed to have been deducted from the annually recurring expenses *e* (or E).

Let *c* = the cost of formation (planting, etc.) which has to be incurred at the beginning of each rotation, occurring, therefore, every *r* years. We may assume that this cost is the same at the beginning of each rotation.

Let *e* = the annual value of all annually recurring expenses, as cost of administration, etc. For our problem, *e* does not include taxes.

Let E = the capitalized value of the annual expenses; that is, $E = \frac{e}{.0p}$.

Let S_e = the expectation value ("soil expectancy value") of the forest; that is, "the sum of the present values of all returns expected from the soil in the course of time, less the present value of all expenses which must be incurred to obtain these returns,"[a] at the beginning of the rotation period, or just after one of the cuttings, Y_r;

The expectation value, or present capitalized value, of a forest in which the above items of revenue and expenditure occur is then represented by the following formula:

$$S_e = \frac{Y_r + T_a\,(1.0p)^{r-a} + \;.\;.\;.\;.\;.\; + T_q\,(1.0p)^{r-q} - c(1.0p)^r}{1.0p^r - 1} - E.^{b}$$

---

[a] Schlich, p. 122.

[b] For those not familiar with the mathematics involved in the above formula, the following explanation may be of service: All the items of revenue and expense are reduced to their present value at the beginning of the rotation period; i. e., just after a final harvest has been cut and before the planting for the next harvest has been made. The final income Y_r will occur after a period of *r* years, and again every *r* years forever. The present value of such an income is, according to a well-known mathematical formula, $\frac{Y_r}{1.0p^r-1}$. The first intermediate revenue appears in the year *a*, and is represented by T_a. In the year *r* it will amount with accumulated interest to $T_a(1.0p)^{r-a}$. The same revenue will appear again after *a*+*r* years, and so on every *r* years forever. The present value of such an income is $\frac{T_a(1.0p)^{r-a}}{1.0p^r-1}$. Likewise the value of the next thinning, coming in year *b* and every *r* years thereafter, is $\frac{T_b(1.0p)^{r-b}}{1.0p^r-1}$; and so on to the last thinning before the final harvest, T_q, whose present value is $\frac{T_q(1.0p)^{r-q}}{1.0p^r-1}$. The cost of planting, etc., is *c*. With accumulated interest this cost will amount, in the year *r*, to $c(1.op)^r$. It will occur again in the year *r* and every *r* years thereafter forever. The present value of all these expenses is $\frac{c(1.0p)^r}{1.0p^r-1}$. The regular annual expenses *e* occur every year forever. Their present value is therefore $\frac{e}{.0p}$=E. The sum of the present value of all these items of revenue less the present values of all the items of expense gives the present value of the forest or its expectation value. Thus:

$$S_e = \frac{Y_r}{1.0p^r-1} + \frac{T_a(1.0p)^{r-a}}{1.0p^r-1} + \;.\;.\;.\;.\; + \frac{T_q(1.0p)^{r-q}}{1.0p^r-1} - \frac{c(1.0p)^r}{1.0p^r-1} - E.$$

This expression reduces to the formula of the text,

$$S_e = \frac{Y_r + T_a(1.0p)^{r-a} + \;.\;.\;.\;.\; + T_q(1.0p)^{r-q} - c(1.0p)^r}{1.0p^r-1} - E.$$

This is the general formula representing all possible systems of forest management. When applied to particular kinds of management the formula may be changed by the omission of certain of its terms. Where no regular system of forestry is practiced, the formula obviously has no application. For the sake of clearness we may classify forests according to their management as follows:

I. Producing a sustained annual yield.
II. Producing a sustained periodic yield,
    1. Clear cutting.
        a. Reproduced by planting.
        b. With natural reproduction.
    2. Selection cutting.
III. Producing an irregular yield (where systematic forestry is not practiced).

I. First, and simplest of all, we have the case of the forest managed so as to produce a sustained annual yield.[a] In this case a regular income is obtained each year, presumably forever. Here r is 1; there is no cost of planting, and hence c is 0; T and A are disregarded, being merged in Y; and we have simply an annual net income representing the difference between the annual yield from all sources and the annual expenses of all kinds. Let this annual net yield=Y. Then the capital value of the forest is obtained from the equation,

$$S_e=\frac{Y}{.0p}.$$

For example, suppose a forest produces an annual net income of 50 cents an acre.[b] . In this and the following examples we assume the rate of interest is 5 per cent. Then $p=5$; $v=0.50$; $S_e=\frac{0.50}{0.05}=10$. That is, we have a forest yielding a net annual income of $0.50 per acre and whose capital value is therefore $10 per acre.[c] This case is like the ordinary business investment.

II. The forest which produces a sustained periodic yield resembles the case just described in that the yield is sustained and fairly regular. It differs in that the principal yield occurs not every year but at longer intervals. The timber may be removed either by clear cutting or by selection cutting. In the first case the timber is practically all removed, and the interval which must elapse before another cutting is the time necessary for the trees to grow to the most profitable cutting age. This case is subdivided according as the forest is renewed after cutting by planting or by natural reproduction.

1, *a*. When a forest is made to produce a sustained periodic yield by clear cutting, reproduced by planting, we have the case to which the general formula applies without change, all the terms being present. Forestry in America, however, has not progressed far enough to enable us to assign values to the terms T and E with any approach to accuracy. It is customary, therefore, to disregard these terms; they, of course, tend to neutralize each other. Indeed, with the present available yield tables and records of planting, the values assigned to Y and c must be more or less arbitrary. The formula thus becomes

$$S_e=\frac{Y_r-c\ (1.\,0p)^r}{1.\,0p^r-1}.$$

---

[a] Of course a forest which as a whole produces a sustained annual yield may be in its various parts managed in any of the other ways. So long as the forest as a whole produces a sustained annual yield, the management of its various parts is a matter of no concern to the problem of taxation, provided a single jurisdiction taxes the whole forest.

[b] The numerical values to be given to the terms in the formula are different, of course, for each species and each locality. This example and those that follow are more or less arbitrary. Their purpose is to illustrate the theory, not to show what may be expected from forestry in any particular case. They are, however, based to a certain extent on actual cases, and are intended to approach with a fair degree of accuracy average conditions in the United States.

[c] The figures in this example are quite conservative. For an example approaching the one given, see Forest Service Bulletin No. 26, p. 49, first example.

For example, suppose a piece of bare or cut-over land is planted at a cost of $7 per acre. The timber is cut after sixty years, when the net value of the yield is $300 per acre. The land is then replanted, and the process repeated indefinitely. Then, $r=60$; $p=5$; $Y_r=300$; $c=7$.

$$S_e=\frac{300-7(1.05)^{60}}{1.05^{60}-1}=\frac{300-131}{17.7}=\frac{169}{17.7}=9.55.$$

This forest therefore yields a net income of $169 per acre every sixty years, and its capital value (or expectation value) is $9.55.[a] The annual income of $9.55 at 5 per cent is $0.48; that is, the forest in question, yielding $169 net every sixty years, is worth exactly the same per acre as a forest or other investment yielding $0.48 every year.[b]

1, *b*. The forest which is made to produce a sustained periodic yield by clear cutting, with natural reproduction, differs from the case just described only in the absence of the item of cost of planting. The formula is, therefore,

$$S_e=\frac{Y_r}{1.0p^r-1}.$$

For example, suppose a forest will produce a net yield of $150 per acre every sixty years, by clear cutting and natural reproduction. Then $r=60$; $p=5$;

$$Y_r=150. \quad S_e=\frac{150}{1.05^{60}-1}=\frac{150}{17.7}=8.47.$$

That is, the forest yields a net income of $150 per acre every sixty years, and its capital value is $8.47 per acre.[c] This forest is worth the same as a forest yielding $0.42 per acre every year.

2. The next case in our classification is the forest producing a sustained periodic yield by selection cutting. Here, instead of taking off all the timber, only a part is removed, the time for removal being selected according to some rule which perpetuates the forest and permits the return, after a certain interval, for another cutting by the same method. The interval is apt to be chosen so that about the same yield will be obtained from each cutting. The forest is perpetuated naturally, and there is no cost for planting. The formula for this case is the same as for the preceding (1, *b*.),

$$S_e=\frac{Y_r}{1.0p^r-1}$$

For example, suppose a forest, under the method of selection cutting, produces a net yield of $15 per acre, and that an equal yield can be obtained every thirty years by the same method of cutting.

$$\text{Here } r=30;\ p=5;\ Y_r=15. \quad S_e=\frac{15}{1.05^{30}-1}=\frac{15}{3.32}=4.52.$$

---

[a] These figures represent a forest in good condition. For examples resembling the above, cf. N. H. Forestry Commission, Report 1905–1906, pp. 235–249; Conn. State Forester Report, 1907, pp. 254–258.

[b] We are here disregarding any extra risk of loss in the case of the planted forest and also the whole question of the proper rate of interest at which to discount forestry investments. These questions are discussed in Chapter VI, pp. 615–618, and in the appendix to Chapter VI, pp. 618–626.

[c] The figures given in the example are probably rather conservative for a first-class forest.

That is, the forest yields a net income of $15 per acre every thirty years, and has a capital value of $4.52 per acre.[a] This forest has the same value as one which yields $0.23 per acre every year.

III. The third group of forests contains all those where forestry is not practiced. There being no regular system of management, it is of course impossible to apply a formula based on regular sustained yield, and accurate calculations of future yield or expectation value are out of the question.

A tax on forest lands, based on earning power, may be applied theoretically in either of two ways, (1) as a tax on income, taxing the net yield of the forest when the timber is cut, or (2) as an annual tax on capital value, the capital value being the true expectation value based on all expected future incomes and expenses. Provided the two tax rates bear the proper relation to each other, the resulting tax burden will be exactly the same, whichever method of taxation is employed.[b] The relation between the two tax rates is expressed by the following equation, where t_i is the rate of the income tax, t_c the rate of the tax on capital value, and p the rate of interest:

$$t_c = t_i \times 0p.$$

For example, if the rate of interest is 5 per cent, a tax of 20 per cent on yield when cut is equivalent to a rate of 1 per cent on capital value.

The tax on yield when cut applies without distinction to all kinds of forests. For this tax it is not necessary to distinguish the different kinds of management, or even to make any special provision for the forest which is not managed under any regular plan. Each forest is simply taxed on its yield whenever any timber is cut.

The tax on capital value, on the other hand, requires the computation of expectation value. This computation differs according to the character of management, and in the case of the forest subject to no regular management is impossible.

The operation of a tax on forests based on these principles may be made clear by a mathematical example corresponding to each of the examples of forest management given above.

For our present purpose we may assume that forests are to be taxed equitably in comparison with other kinds of wealth which are under the general property tax. The proposition to offer special encouragement to forestry by means of taxation at a lower rate than other kinds of wealth have to bear is discussed elsewhere. Here we assume the ideal of an equal burden of taxation on all kinds of wealth in proportion to income. Let us assume, by way of example, that other forms of wealth are being taxed at the average rate of 1 per cent of the true value, under the general property tax.[c]

The California tax commission in 1906 adopted 1 per cent as representing the average burden of the general property tax on wealth in general in California. "Report of the Commission on Revenue and Taxation of the State of California, 1906," p. 98-100.

With an interest rate of 5 per cent, this is equivalent to a tax of 20 per cent upon net income. Applying the two methods of taxation in turn to each of the examples of forest management given above, we have the following result:

(1) The case of the forest producing a sustained annual yield is the simplest. The net income is $0.50 per acre annually. Its capital value is $10 per acre. If taxed on yield, this forest would pay an annual tax of 20 per cent of $0.50, or $0.10 per acre. If taxed on capital value, it would pay annually 1 per cent

---

[a] These figures are probably rather conservative. For a similar example, cf. Forest Service Bulletin No. 26, p. 49, second example. This example was a forest of spruce with some hard woods, only the spruce being figured in the value of the cut. A number of other examples more or less similar to the one in the text may be found in the various forest working plans issued by the Forest Service and printed in its Bulletins.

[b] This assumes also, of course, that the rate of interest employed in the calculation of expectation value is the correct one for the circumstances.

[c] In Connecticut the average tax rate in 1907 was 1.3 per cent on an assessed valuation of 85 per cent. This is equivalent to a rate of 1.105 per cent on the true value. "Information relative to the Assessment and Collection of Taxes, 1908." Published by the Connecticut tax commissioner, pp. 20-21.)

of $10, or $0.10 per acre. The tax is evidently the same, whichever basis of assessment is employed.

(2) The next example is that of the forest producing a sustained periodic yield by clear cutting, reproduced by planting. The net income, or the value of the cut less expenses, is $169 per acre, and this income occurs every sixty years. The capital value of the forest is $9.55 per acre. If taxed on yield, this forest would pay a tax of 20 per cent of $169, or $33.80 per acre, paid every sixty years at the time of cutting. If taxed on capital value, the tax would be 1 per cent of $9.55, or $0.095 per acre, paid annually. The present value of $33.80 paid sixty years from date and every sixty years thereafter (interest being at 5 per cent) is $\frac{33.8}{1.05^{60}-1}=\frac{33.8}{17.7}=\$1.91$. The present value of $0.095 paid annually forever is $\frac{0.095}{0.05}=\$1.90$. The mathematical identity of the two methods is evident.

(3) The forest producing a sustained periodic yield by clear cutting, with natural reproduction, differs from the preceding case only in the absence of an item of cost of planting to be deducted from the yield. In the example given the net yield is $150 per acre, occurring every sixty years. The capital value is $8.47 per acre. The tax based on yield would be 20 per cent of $150, or $30, paid every sixty years. The tax on capital value would be 1 per cent of $8.47, or $0.085, paid annually. The present values of these two taxes are, respectively, $\frac{30}{1.05^{60}-1}=\$1.69$, and $\frac{0.085}{0.05}=\$1.70$.

(4) Where the forest produces a sustained periodic yield by selection cutting, the expectation value is computed by the same formula as in the preceding case. In the example given the net income is $15 per acre, occurring every thirty years. The capital value is $4.52 per acre. The tax based on yield would be 20 per cent of $15, or $3, paid every thirty years. The tax on capital value would be 1 per cent of $4.52, or $0.045, paid annually. The present values of these two taxes are, respectively, $\frac{3}{1.05^{30}-1}=\$0.90$ and $\frac{0.045}{0.05}=$ $0.90, demonstrating the identity of the two methods of assessment.

(5) Where no regular management is employed, and the yield comes at irregular intervals and in irregular amounts, it is obvious that mathematical examples would be of no service. It is equally obvious that this kind of forest presents no theoretical difficulties in the case of a tax on yield when cut, but that the annual tax on capital value is impossible, since there is no way of calculating expectation value.

Assuming that the correct basis of taxation is income, and that timber lands are to bear the same relative burden of taxation as other kinds of wealth, the theory of the correct taxation of timber lands is simple. The foregoing examples are sufficient to demonstrate this. Forest lands may be taxed in one of two ways: (1) Levy a tax on the value of the net yield whenever any timber is cut, at a determined rate, assumed to represent fairly the burden of taxation on other kinds of income. This method applies without distinction to the forest producing an annual sustained yield and to the one whose yield is periodic. The difference is that in the one case the tax is paid annually; in the other it is paid at regular but longer intervals. It also applies without difficulty to the forest whose yield is irregular. (2) Estimate the capital value of the forest (i. e., its expectation value based on all future expected incomes and expenses) and levy the tax at a determined rate equivalent to the income tax rate which represents fairly the burden of taxation on other kinds of wealth. The rate of the tax on capital value is the rate of the income tax multiplied by the rate of interest. This method also applies to any forest which is producing a sustained annual or periodic yield. In the case of the annual sustained yield, the calculation of capital value is very simple, the capital value being the quotient of the annual income divided by the rate of interest. In the case of the periodic yield the problem is more complicated, requiring the calculation of the present expectation value of the forest based on all future expected revenues and expenses. This method can not be used in those cases where no regular management is in operation, or where the yield is so irregular as to prevent the accurate calculation of expectation value.

II. THE RATE OF INTEREST.

A most important factor in the calculation of expectation value is the rate of interest. In the examples in Section I of this appendix 5 per cent has been chosen as the rate of interest, and this rate has served as well as any other for the illustration of theoretical principles. The selection of this particular rate, however, has not been meant to carry with it any assumption that 5 per cent is in fact the correct rate at which to capitalize forest investments, nor that the selection of the rate of interest is a matter of slight importance. It is really of the most vital importance; indeed, it is hardly an exaggeration to say that it is the crux of the whole theory of the tax on expectation value. Its importance can readily be seen by a glance at the following table, which shows the expectation value and the amount of the annual tax on capital value in each of the examples discussed above, where different rates of interest are used in the calculation:

Tax on expectation value.

Rate of interest.	Example 1.		Example 2.		Example 3.		Example 4.	
	Expectation value.	Tax.	Expectation value.	Tax.	Expectation value.	Tax.	Expectation value.	Tax.
Per cent.								
3	$16.67	$0.17	$52.92	$0.53	$30.67	$0.31	$10.49	$0.10
4	12.50	.13	23.84	.24	15.79	.16	6.70	.07
5	10.00	.10	9.55	.10	8.47	.08	4.52	.05
6	8.33	.08	2.16	.02	4.69	.05	3.16	.03
7	7.14	.07	−1.87	−.02	2.63	.03	2.27	.02
10	5.00	.05	−6.04	−.06	.49	.005	.91	.009

The results of using different rates of interest are most remarkable in example 2, which is due to the presence of an original cost of planting, which increases enormously as the rate of interest is raised, until at 7 per cent this cost eats up the entire yield of the forest. This is the only case in which the expectation value can become negative. The other examples, however, are scarcely less eloquent in their testimony to the overwhelming importance of the rate of interest. When we see that a change of one unit in the rate of interest may double or even treble the amount of the tax, we begin to realize that if our tax system is to be based on expectation value all our search after an equitable tax will be a farce unless means are taken to correctly determine this factor of the problem.

In the brief time which the writer has had at his disposal for the preparation of this report it has been impossible to give the subject the thorough investigation which its importance deserves. Indeed, for all the practical purposes of this report, such a study would have little bearing, since, as is shown in the text of Chapter VI, the tax on expectation value must be rejected on other grounds as not capable of practical application under present American conditions. This subject will therefore be passed with the following brief suggestions:

That the question has never received proper investigation is evident from the character of its discussion in the technical works on forestry. In working out problems of expectation value, these works use rates of interest which are almost certainly too low, if forestry is to be considered on a commercial basis. For example, Endres uses 3 per cent in calculating expectation value.[a] Schlich, after a discussion covering three pages, decides on 2½ per cent, basing his decision mainly on the fact that at the time he was writing that was the rate paid by British consols.[b] Fernow argues in favor of a low rate of interest,[c] on the grounds that interest rates are likely to fall in the future, that forests will generally be a safe investment, and that the price of wood is likely to rise. He concludes that, since trust companies and savings banks are making long-time investments at 3 and 3½ per cent, we may safely use those rates or even lower ones in calculating the value of forest investments. In an example on another page, however, he uses 5 per cent.[a]

[b] Schlich, "Manual of Forestry," Vol. III, 3d ed., pp. 113–116.

[c] Fernow, "Economics of Forestry," pp. 214–215.

These examples will illustrate the reasoning commonly employed on this subject, the conclusion being that forest investments should be capitalized at a relatively low rate of interest, not higher than 2½ or 3 per cent. This conclusion may possibly be valid for the settled conditions of forestry which prevail in certain parts of Europe, though even this is open to question. But for conditions such as prevail in America such reasoning and such a conclusion can not be accepted.

Instead of being lower than the ordinary commercial rate, the writer is satisfied that the rate of interest for forest investments should be fully as high as the rate on ordinary investments, or even considerably higher. Forestry is a business of a peculiar character. In the first place, the risk is very great. The danger of fire is so great that no insurance company will take the risk. There is also the risk of injury by insects, wind, etc. These risks must be taken account of in the rate of interest, and it will require more than a slight increase in the rate to fully compensate for them. To put forest investments on a par with government bonds and the better class of trust company and savings bank investments is absurd under present American conditions.

But the circumstance which above all others makes forestry a business by itself is the very long period which must generally elapse before the investment begins to yield an income. The investment of $1,000 in a perpetual annuity of $30 or $40 a year is one thing; to put capital into an investment from which no income is to be expected for fifty or sixty or even one hundred years (very probably not till after the death of the investor) is a very different thing. Innumerable investments of the first kind are being made every day, and we can determine the prevailing rate by a glance at the dealings on the stock exchange. Investments of the second kind are so rare that we are unable to say from actual dealings what the rate should be. The comparison of future with present good, on which rates of interest depend, is a psychological process, and is influenced by a multitude of considerations. One of the most important of these is the remoteness of the future good, and it is certain that the rate at which men discount future events tends to increase with the remoteness of the event. Many a man who is satisfied with an investment which yields him 3 or 4 per cent at once would not consider for a moment an investment at the same rate whose income was to commence sixty years from date. It is safe to say that, other things being equal, men will not be tempted by forestry investments unless the rate of interest is considerably higher than that of investments whose income begins at once. It is clear that we can not put forestry on a par with the better investments of trust companies and savings banks.

Even a brief examination will show the weakness of some of the arguments cited above in favor of a low rate of interest. The assumption that the rate of interest tends to fall is belied by recent history. Schlich, writing in 1895, based his rate on British consols, which paid 2½ per cent, and he has made no change in this paragraph in his third edition published in 1905. But to-day British consols yield 3 per cent on their market price, and French and German government bonds yield even higher returns. Fernow's book was published in 1902, yet even this brief time has seen a considerable rise in interest rates, and many a savings bank to-day is paying 4 per cent to depositors. On account of the depreciation of our monetary standard, resulting from the tremendous production of gold, interest rates have been rising for the past decade, and the same influence is more than likely to cause a further rise in the future. So far as the future of the rate of interest is concerned, the effect should be to cause a higher rather than a lower rate on deferred incomes.

That the price of wood is likely to rise, and so increase the profits of forestry, can not be denied. This circumstance, however, should not properly enter into the determination of the rate of interest. It should rather be taken account of in estimating the value of the future yield of the forest (the terms Y and T in the formula). Any proper estimate of the value of future yield will take

---

[a] Fernow, "Economics of Forestry," p. 251.

into account the probable increase in the price of timber. This factor being thus accounted for, there is no reason for lowering the rate of interest on this account.

We may conclude, then, that as compared with ordinary investments, the income of forestry should be capitalized at a relatively high rate of interest. Further study would probably show that, if the rate of five per cent adopted for the examples above is not the correct one, it errs in being too low rather than too high.

CHAPTER VII.

PRACTICAL CONSIDERATIONS AND PROBLEMS OF ADMINISTRATION.

The practical difficulties in the way of any plan of tax reform in the United States are tremendous. The path toward scientific forest taxation is sure to be strewn with obstacles, more or less serious. The tax on yield when cut has been advocated as an underlying principle. In putting this principle into operation no two States would necessarily adopt exactly the same administrative methods or machinery. This report obviously can not go into local conditions or into minute details of administration. We must, however, discuss some of the general problems of administration and look into some of the serious practical objections which may be urged against the tax on yield when cut. The following suggestions are offered:

I. THE BASIS OF ASSESSMENT.

Shall the tax be assessed upon the gross or upon the net yield of the forest? The ideal basis for any tax is net income. Practically it is often advisable to use gross income. In the case of forest taxation the stumpage value of the timber cut would probably be the best basis of assessment. In most cases this comes very near the net yield, and it is also the simplest basis for administrative purposes.

II. EQUALIZING LOCAL INCOME.

The first difficulty in the way of the tax on yield is that it would apparently result in an irregular and uncertain revenue for many towns and counties. Three alternative plans are suggested for meeting this difficulty.

(*a*) Let the tax be administered by the State. Let a rough estimate be made of the probable average annual yield of the forests in each town or county. Applying the tax rate to this average yield will give approximately the average annual revenue which the town or county may expect from its forests. Then let this amount be paid to each town or county annually by the State. Whenever any timber was cut in the town or county the State would collect the tax. An account would be kept by the state treasurer in which the town or county would be debited with the annual payments to it from the State, and credited with all taxes collected from the forests within its borders. At stated intervals a balance would be struck between these debits and credits with accumulated interest to date. The balance on either side would be carried forward to the next time of settling. A large balance on either side would be avoided by altering the amount of the annual payments from time to time as experience showed they were too high or too low. Such a plan would not require an exact calculation of expectation value, since no permanent injustice could result from errors in the calculation of the annual payments from the State to the towns or counties. This plan makes the State the administrator of the forest tax and the banker for the towns or counties, thus guaranteeing to each a fairly regular income, probably more regular than the income from taxation of forest lands to-day. The State itself has a large enough territory, so that the tax would produce a fairly regular income for the whole State.

(*b*) The same result might be accomplished in another way. Let a nominal annual tax be collected from the owners of timber lands. When the timber is cut collect the tax on the yield and allow a deduction for the previous annual payments with interest to date. If, through a mistake, the annual payments had been excessive, so that, with interest, they exceeded the tax on the yield when finally cut, a rebate would be due the owner. This plan would be necessary only for forests producing an intermittent or irregular yield. Where a sustained annual yield was produced, the tax would simply be collected each year at a certain percentage of the yield. This plan has the advantage of great simplicity. It could be administered either by state or local officers, and the necessary bookkeeping would be very simple.

(*c*) A third way of avoiding the difficulty of irregular local revenue would be to make the forest tax a state tax, pure and simple, compensating the local division in some equitable way, as by a payment from the State according to some definite rule, or by the State surrendering to the local divisions some other source of revenue. Some such arrangement might be introduced by a State which happened to be remodeling its tax system as a whole.

Each of those plans has advantages and difficulties. Probably the second would best fit present conditions in the majority of States. Still other plans might be suggested. At any rate it seems reasonable to believe that no insuperable obstacle to the tax on yield will be found here.

III. THE SMALL WOOD LOT

Another administrative question arises here. To tax every farm wood lot whenever a little timber is removed would be altogether too costly and cumbersome. It might be advisable to tax wood lots having less than a certain area by a somewhat different method. Lots might be classified under some simple rule into a few grades according to quality, the tax per acre being fixed for each grade at a fairly low figure and collected annually, with an additional tax on the yield if the timber were ever entirely cut off.

IV. NECESSARY RESTRICTIONS.

This system of a special timber-land tax must apply to bona fide timber lands only. For example, the laws must be so drawn as to prevent the holding of land without taxation for merely speculative purposes under the guise that it is timber land. It might be advisable to restrict the forest tax to lands not exceeding a certain value per acre, as is done in many of the present exemption laws; or by some provision in the statutes to enforce the actual use of the land for producing timber. It should not be a very difficult matter to provide the proper safeguards against this danger.

V. CUTTING IMMATURE TIMBER.

It may be necessary to make some special provision for the man who, having planted trees, changes his mind and cuts them off before they have grown to any great value. The small tax on the value of the cut might not be a fair compensation for the preceding years of exemption. This situation might be provided for by a simple classification of such lands according to quality and age of trees, with taxation at arbitrary rates for each class.

VI. MATURE TIMBER.

Shall the owner of mature timber be allowed to hold it indefinitely without taxation, or shall he begin to pay taxes as soon as the timber reaches maturity? If it is considered advisable to require some taxes from mature timber which is not cut, some plan must be devised. Here again the object might be accomplished by means of a simple classification of mature-timber land, with a small tax per acre, the regular tax on yield being collected when the timber was finally cut.

VII. TRANSITION PROBLEMS.

Some administrative problems would arise due to the transition from the present to the new system. For example, a mature forest which is cut just after the new plan has gone into effect could not equitably be taxed on its yield, since it has presumably paid its full share of taxation during all the years that the trees have been growing up. Similarly, an equitable compromise would be necessary for timber which was partly grown when the new plan was adopted.

These suggestions regarding practical problems make no pretense to having covered all the possible complications which might arise under special conditions. With regard to all such problems as these, involving special circumstances here and there, but not the general run of ordinary cases, the writer is strongly convinced that the solution should be in the adoption of certain simple, even arbitrary, working rules which aim to secure certainty and ease of administration rather than any nice adherence to theoretical principles.

VIII. EFFECT ON REVENUE.

It may be asked, what will be the effect of the tax on yield upon the revenue of the States and local divisions? Strictly speaking, this question should be answered for each State separately in the light of local conditions. In some cases it is possible that the adoption of the tax on yield might cause some temporary disturbance of the revenue system. In general, it is not believed that this method of taxing timber lands will lead to any serious reduction of revenue. If, as the evidence seems to show, forests are as a rule not excessively taxed to-day, there is no reason to expect any great reduction of revenue through the adoption of the tax on yield. Eventually revenue will be increased by a method of taxation which does not prevent the development of forestry. Forests paying a moderate tax are better than abandoned lands paying no tax at all. This is assuming always that the rate of the forest tax is selected so as to make forests bear the same relative burden as other kinds of wealth. It may be considered advisable to attempt to encourage forestry by a special low rate. In this case some revenue will of course be sacrificed.

IX. CONSTITUTIONALITY.

The plan of a tax on the yield of forests at a special rate, in lieu of the general property tax, will be unconstitutional in many of the States of the United States. These state constitutions stand to-day in the way of many plans for reform in state and local taxation. The movement toward their amendment is growing as part of the general programme of tax reform. If the plan of forest taxation here proposed wins favor, it will simply be an added argument for the speedy amendment of those state constitutions which are now blocking the progress of scientific tax reform.

X. TAXATION OF FORESTS IN EUROPE.

This topic is mentioned here for want of a better place. On account of the limited time for the preparation of this report, it has seemed best to omit a discussion of this subject altogether. Forestry conditions in Europe are so much more advanced than with us that the problem of taxation is less difficult. The prevailing tax systems of European countries are likewise different from ours, the general property tax having been abandoned long ago. In general, European countries base their forest taxation on a combination of ground tax and income tax. The ground tax is based on the average productive power of the forest, estimated in advance from time to time. The income tax is based on the actual income produced.

CHAPTER VIII.

CONCLUSIONS.

It is with a certain feeling of hesitancy that the following conclusions are presented. The time allowed for the preparation of this report has been out of all proportion to the magnitude and importance of the subject. Moreover, the writer expects to make a further thorough study of this subject in the immediate future. The conclusions presented in this preliminary report are therefore somewhat tentative, and it is realized that some of them may possibly have to be modified after further investigation. In the main it is believed that they will prove to be in harmony with the facts.

I. CONTRACT BETWEEN STATE AND FOREST OWNER.

Many schemes of forest taxation have been proposed involving a contract by which the State offers some form of taxation assumed to be particularly favorable to timber lands on condition that the owner agree to plant, cultivate, or maintain his forest according to some specified plan or under the direction of some state authority. This idea has something to be said in its favor; it is also open to some serious objections. At present the writer does not feel prepared to pass judgment upon it. The plan of taxation outlined in this report does not contemplate such a contract. However, there is nothing in the principles here laid down inconsistent with the adoption of such a contract should it be deemed advisable.

II. SPECIAL FAVORS TO FORESTRY THROUGH TAXATION.

Throughout this report we have gone on the assumption that forests should bear the same relative burden of taxation as other kinds of wealth in proportion to income. As has already been shown, however, having once adopted the principle of the tax on yield, it is a simple matter to give any desired favor up to a complete exemption from taxation by merely fixing the rate of the tax. We have, therefore, in no way prejudiced the case against special favors to forestry.

This subject leads us out upon a broader field than the mere problem of correct taxation. Two questions may be asked: (1) Is the proposed encouragement to forestry by a low tax rate a proper use of the taxing power? In general, there would seem to be no reasonable objection to such a policy provided the end sought be an increase of the public welfare and provided the means be effective. Such a programme should, however, be carried out with great caution in order to prevent doing injustice to certain localities. The gain to be obtained from encouraging forestry is to the people in general, and the cost should be borne by those who enjoy the gain, not by the people of the locality where the forests happen to be. If special rates of taxation are granted to forests some arrangement must be made whereby the localities affected will be compensated for the resulting loss of revenue. (2) To what extent will the reduction of taxes prevent the destruction of forests and encourage the practice of forestry? In answering this question we are helped by the evidence presented in preceding chapters of this report. This evidence forces us to the conclusion that in this matter no great relief is to be looked for through the reduction of taxation. It has been shown that taxation has not been the cause of the cutting of our forests, and it is idle to hope that any reduction in taxation will have more than a slight influence in preventing further destruction. Taxation does not explain the present absence of forestry in America, and until other forces have become strong enough to lead to its practice special tax rates will probably not have any great influence.

It may well be that in certain places local conditions are such that great good might be accomplished by a reduced tax on forests. Where this is the case, no objection can be raised to such a programme, provided both general and local interests be safeguarded. But the solution of the general problem of forestry lies mainly outside the realm of taxation.

This matter of a reduced tax rate must of course be distinguished from the question of just and certain taxation. We have already shown that forestry can hardly be expected to flourish until our present tax methods are replaced by a system which insures reasonable equity and certainty. The writer is of the opinion that if a tax at once equitable and dependable is guaranteed, the business of forestry will not need to ask special favors.

III. SOME ADVANTAGES OF THE TAX ON YIELD.

The general advantages of this method of taxing timber lands have already appeared throughout the preceding discussion. It remains here to call attention to certain features which have perhaps not received sufficient emphasis heretofore. In the first place the tax on yield is based upon correct principles. It bears a definite relation to income. Under this method it will be possible to make the tax on forests equitable as between different forest owners and as compared with other kinds of wealth. Still more important, the tax will be certain, a definite part of the yield, which the owner may calculate in advance and depend upon. If fire or accident destroys the yield the tax is reduced accordingly. Being due when the timber is cut, it will be paid at the time most convenient for the taxpayer. Also, being paid when the timber is cut, there will be no inducement to cut timber in order to avoid taxes or to get money with which to pay taxes. There is nothing in the tax to lead to the abandonment of cut-over lands or to prevent reforestation, provided the land can be profitably forested at all. For these and other reasons, the tax on yield, instead of being an obstacle to the practice of forestry, will be a distinct encouragement.

IV. GENERAL SUMMARY AND CONCLUSION.

We have seen that in spite of special statutes in some States timber lands are actually taxed under the general property tax everywhere in the United States. The general property tax is a thoroughly discredited method of taxation. It has proved itself a complete failure, and was abandoned long ago by every [illegible]portant nation except the United States. The general property tax is especially burdensome in the case of forests, because the annual increase in the value of the trees is not taken as income, but is stored up in the forest, there to be taxed over and over again till the timber is finally cut.

In certain parts of the country, and in individual cases almost everywhere, the taxation of timber lands has undoubtedly been excessive and has produced serious results on the forests. As a general rule, however, due to the prevailing habit of under assessment and the lax administration of the law, forests have not been taxed excessively. It also appears that in most cases taxation has not been responsible for the destruction of our forests or for the failure to reforest cut-over lands.

The real problem of forest taxation is in connection with the future of our timber lands rather than with their past. The preservation of the forests is a matter of the utmost importance. So far our forests have been exploited with little or no regard for the future. But the present methods can not last much longer. Forestry must come some time, and its early coming is a thing greatly to be desired. And whenever we are ready to seriously undertake it we will find our present methods of taxation a severe handicap. Strictly enforced, according to the letter of the law, the annual tax on the full value of the land and standing timber is almost sure to result in excessive taxation, and the timber owner can not count on the continuance of the present lenient enforcement of the law. Even if the tax might not be excessive, its uncertainty would be a serious obstacle to investment. We can hardly hope to see the general practice of forestry as long as the present methods of taxation continue.

To be equitable, taxation of timber lands like taxation of anything else should be based on income or earning power. This may be accomplished in the case of forests either by a tax on the yield when cut or by an annual tax on the capital value of the forest, based on all its expected future incomes and expenditures, i. e., on what the foresters call "expectation value." At present and for some time to come the tax on expectation value can not be generally applied to America on account of the slight development of forestry and the absence of the necessary statistical data, such as yield tables, etc. On the other hand, the tax on yield has decided advantages, both theoretical and practical, in its favor. Among others, it does not have to take account of the rate of interest, of the risk of loss by fire, or of future prices of timber.

The tax on the yield when cut is advocated as the principle on which any scientific system of forest taxation should be based. In putting this principle into practice many problems must be met. Suggestions have been made regarding the solution of some of the more important of these. It is not believed that any of these problems will prove incapable of solution.

With regard to its effect on revenue, there is little to be feared from the tax on yield. Eventually, revenue will be increased by a method of taxation which does not prevent the development of forestry. Forests paying a moderate tax are better than waste lands abandoned and paying no tax at all.

Too much confidence should not be placed in the plan to levy a special reduced tax on timber lands in the interest of forestry. It is not likely that a mere reduction of taxation will have any great influence in stopping the destruction of the forests or inducing the practice of forestry.

The tax on yield has many decided advantages. It avoids the evils of the general property tax. It is equitable and certain. It is in harmony with the peculiarities of the business of forestry, and will be a distinct encouragement to the practice of forestry. Its adoption by the States would remove one obstacle to the perpetuation of the nation's forest resources.

REDUCTION OF TIMBER SUPPLY THROUGH ABANDONMENT OR CLEARING OF FOREST LANDS.

By W. B. Greeley,
United States Forest Service.

SUMMARY.

The original forested area of the United States, of approximately 900,000,000 acres, has been steadily reduced by the demand for agricultural land and the increasing consumption of lumber and other forest products. The total area of improved farm land in the United States was 118,457,000 acres in 1850; 163,110,000 acres in 1860; 188,921,000 acres in 1870; 284,771,000 acres in 1880; 357,616,000 acres in 1890; 414,485,000 acres in 1900, and approximately 447,762,000 acres in 1907.

Of the total area of improved farms in 1907, not less than 65 per cent, or 292,000,000 acres, has been drawn from the original forests of the country.

The area of timbered land cut over for all forms of forest products was 2,058,000 acres in 1860; 3,468,000 acres in 1870; 4,764,000 acres in 1880; 5,841,000 acres in 1890; 8,577,000 acres in 1900, and 9,429,000 acres in 1907.

The results of the enormous drain from these two sources upon the original forests of the United States are shown by the following figures:

In round numbers, of the virgin forests of the country, in 1907 292,000,000 acres had been put into improved farms and are presumably withdrawn for all time from timber production; 335,000,000 acres, or 37 per cent of the original area, still contain merchantable timber; 180,000,000 acres are completely cut over, but in process of restocking with forest; and 65,000,000 acres, also completely cut over, are not restocking and will not produce a new growth of trees without artificial assistance.

Of the 9,429,000 acres of forest land which were cut over in 1907, 1,049,000 acres were put into farms; 5,642,000 acres are restocking with forest, and 2,737,000 acres are not restocking with forest. Of the total remaining area of merchantable timber, one-thirty-sixth is, therefore, being cut over annually. Of the acreage annually cut over, 11 per cent is put into farms; 60 per cent is restocking with forest and can be counted upon to a greater or less extent for future timber supply, and 29 per cent is not restocking and can be made of future value as timber-producing land only by artificial reforestation.

Estimating the annual growth per acre on all classes and types of forest land in the United States at 72 board feet, the original forests of the country produced annually 64,800,000,000 board feet of timber. The present forested area of the country, after the drain indicated to supply farming lands and various forest products, is producing a little more than 37,000,000,000 feet, or less than 58 per cent of the original production. The withdrawal of lands for agriculture, and methods of logging which leave the cut over areas unproductive of timber, have therefore caused a loss of 25,704,000,000 board feet in the annual wood crop. Of this loss, 21,000,000,000 board feet, is unavoidable, and is due to the necessary increase in the area of farm land; but the remainder of 4,680,000,000 feet is from the areas of cut over land which are not put into farms, but which, because of the methods of logging employed and the lack of protection, are not restocking with forest. This loss should be classed as national waste.

With the farms encroaching upon the forested area at the rate of 1,050,000 acres a year and with the area of cut over land which is not restocking increasing at the rate of 2,737,000 acres a year, the annual loss in timber production is increasing at the rate of 272,664,000 board feet a year. Of this increasing yearly loss of growth 75,600,000 feet may be classed as necessary, because it results from the increased acreage put under tillage; the remainder, or 197,064,000 feet, is unnecessary and can be avoided by improved methods of exploitation and protection.

The significance of this loss in the annual production of timber in the United States lies in its cumulative effect upon future supplies. If the present rate of increase in the areas of forest land which are cleared for tillage and in the areas which are cut over under such conditions that they do not restock with forest is maintained, the loss in growth of timber will amount in ten years to 272,146,000,000 board feet. If farm land is eliminated, the loss resulting from unproductive cut-over lands alone will, in the same period, aggregate 57,638,000,000 board feet. In twenty years the loss from both sources will become 596,452,000,000 board feet, and the loss from unproductive cut-over areas alone 124,144,000,000 board feet.

It is impossible to place exact limits upon the future increase in the acreage of improved farm land because of the many variable factors which enter into this question. The trend of conditions in this respect, however, is indicated by the following figures. One and nine-tenths acres of grain are required to support each person in the United States, exclusive of exports of grain or grain products of any character. In the twenty-seven years from 1881 to 1907, inclusive, the population of the United States increased at the average rate of about 1,290,000 souls a year. During the same period the grain area of the country required for home support alone increased at the rate of 2,400,000 acres annually. If the population continues to increase, not at the same ratio as during the past twenty-seven years, but at the same average number of persons per annum, the ratio of increase steadily diminishing, the country in 1950 will contain 55,470,000 more people than at present. If the same conditions as regards average grain production per acre and average consumption per capita hold true until 1950, the country will require by that year an additional grain area for home consumption only of 82,598,000 acres. The grain area at present forms 41 per cent of the total acreage required for all agricultural products. If this ratio still holds the total increase in improved farm land required for home consumption by 1950 will reach 202,336,000 acres. In this calculation, however, allowance has been made for possible increase in the yield per acre.

In the arid portion of the United States expansion in the acreage of farm land is limited closely by the water supply available for irrigation. The total irrigable area in the West is estimated at 60,000,000 acres. The drainage of morasses would add large areas of highly fertile land. It seems evident that not less than 100,000,000 acres of forest must be withdrawn from timber production by 1950 in order to provide a sufficient food-producing area to make the nation self-supporting.

If the present rate of increase in the cut-over areas which are not reproducing is maintained until 1950, the unproductive cut-over land will in that year amount to 182,000,000 acres. With the further withdrawal of 100,000,000 acres from the timber-growing area required by the demand for agricultural crops, the acreage of forest-producing land of all classes will by 1950 be reduced to 298,000,000 acres or about one-third of its original extent. The original annual growth of timber of 64,800,000,000 board feet will by 1950 be reduced to 21,456,000,000 feet.

Looking toward the distant future it will be of greater value to indicate corresponding conditions in the older and much more thickly settled countries of Europe than to attempt to use the present bases of estimate or comparison. The United States, for example, has a present population of 28.62 persons per square mile, as compared with 191.68 per square mile in France. The United States requires 55.11 acres in grain in each square mile in order to support its population. France requires, or would require if all the grain consumed were grown at home, 176 acres in each square mile. In the United States the annual consumption of grain per capita is 43.85 bushels, while in France it is a little over 21 bushels. If the United States should ever attain a density of population equal to that in France, which in this country would mean a total of 571,000,000 people, and should at the same time bring its average consumption per capita down to the French basis, we would require a grain area of 523,000,000 acres, and a total area in farm crops of 986,000,000 acres.

To make a less extreme comparison, if this country attained a density of population equal to that of Europe as a whole, it would contain 103 persons to the square mile, or a total of 306,000,000. If we increase the average production of grain per acre from its present figure to 29 bushels, the consumption per capita remaining unchanged, 1½ acres of grain would be sufficient to support each person in the United States, or a total grain area of 459,000,000 acres. An approximately equal area would be required for other agricultural products, making the total area under tillage 918,000,000 acres. This would require an addition of 261,000.000 acres of agricultural land to the area estimated for 1950 and would reduce the forest resources of the country to about 219,000,000 acres including the 182,000,000 acres which as has been shown will not restock itself with timber without artificial assistance.

At the same time, if the production per acre could be brought up to the highest level reached in Europe, as in England which produces nearly 11 bushels of grain per acre more than the United States, and if the consumption per capita were reduced to the standard of living now obtaining in Europe, a population of 300,000,000 could be amply supported by the United States with no increase in its present area of improved farm land. The indications are conclusive, however, that such changes will take place very slowly and that as far ahead as can now be foreseen this country must face a steady reduction in its forest area to meet the insistent demand for agricultural land.

The area included in the present boundaries of the United States contained, in its virgin condition, approximately 900,000,000 acres of forest. With the spread of settlement and growth in population, this area has been steadily reduced in order to satisfy two economic wants, viz, the demand for agricultural land and the steadily increasing requisition of lumber and other forest products. The increased acreage of improved farm land from decade to decade from the census of 1850 is indicated in the following table derived from the reports of the census:

TABLE I.—*Area of improved farm land in the United States from 1850 to 1907.*

NOTE.—The figures for 1850 to 1900, inclusive, are taken from the census reports.

Of the total area of improved farms in 1907, not less than 65 per cent has been drawn from land which was originally timbered. In other words, approximately 292,000,000 acres of the original forests of the United States had, prior to 1908, been cleared and devoted to agriculture.

The drain upon the forest areas during the last fifty years to supply the demand for lumber and other forest products is indicated in the two following tables. Table II shows by States the annual cut of lumber, exclusive of other forest products, by decades, from 1860 to 1907. Table III shows the estimated area cut over annually during the same period for all forms of forest products.

TABLE II.—*Cut of lumber in the United States from 1860 to 1907.*

[In thousands of board feet.]

NOTE.—The figures for 1880 to 1907, inclusive, are taken from the census reports. The census reports for 1860 and 1870 give only the value of lumber cut in the respective States. The best estimates from other sources indicate a total cut in the United States of approximately 8,000,000,000 feet in 1860 and 13,000,000,000 feet in 1870. By comparing these figures with the total value of the lumber cut, as given in the census reports for the same years, an average value per thousand feet of $12 in 1860 and $16 in 1870 is indicated. The value of the cut in each State, as given in the census, was converted into board feet by using these divisors for the respective years.

TABLE III.—*Estimated area cut over annually in the United States from 1860 to 1907, including cordwood and all forms of forest products.*

NOTE.—The figures for 1907 are based upon statistics collected by the Forest Service during 1908, by counties and States, for all forested portions of the United States. A comparison of the total area cut over in 1907 with the total lumber cut of that year, the Pacific Coast States excepted in both cases, indicates that for every thousand feet of lumber manufactured a total area of approximately 0.268 acre is cut over for all forms of forest products. By the use of this factor, the annual cut of lumber in each State for the years preceding 1907, as given in the foregoing table, was converted into the area cut over for all forest products. This method is based upon the assumption that the cut of minor forest products has increased proportionately with the cut of lumber. Separate factors were worked out for the States of California, Oregon, and Washington by comparing in each case the cut of 1907 in board feet and in acres. These factors are, respectively, 0.128 for California, 0.073 for Oregon, and 0.046 for Washington.

The totals of the foregoing table show forcibly the steady increase in the drain upon the forest areas of the United States required to supply the consumption of lumber, cord wood, pulp, and other wood products, reaching in 1907 a figure close to 9,500,000 acres.

The next question which presents itself is, Just where do we now stand both as regards remaining areas of merchantable timber and possibilities of future production on areas previously cut over? Table IV gives an estimate of the area in each State which still contains merchantable material, although in several States a considerable percentage of this area has been culled of a portion of the stand, together with those cut-over areas which are restocking with forest and those which are not restocking, respectively.

TABLE IV.—*Areas of merchantable timber, cut-over land which is naturally restocking with forest, and cut-over land which is not restocking.*

Total	334,923,759	180,006,217	65,046,669

NOTE.—This table is compiled from reports by county clerks during the summer of 1908. The totals for several States as thus obtained are undoubtedly incorrect, and are presented simply as a basis for discussion.

It appears, therefore, that of the originally forested area of the United States 292,000,000 acres have been put into improved farms and are presumably withdrawn for all time from timber production; approximately 335,000,000 acres, or about 37 per cent of the original area, still contain merchantable timber; 180,000,000 acres are completely cut over but restocking with forest; and a little more than 65,000,000 acres, also completely cut over, are not restocking and will not produce a new growth of trees without artificial assistance.

The United States is cutting annually approximately 9,500,000 acres, or about one thirty-sixth of its total area, of merchantable timber. Of the acreage annually cut over, it is estimated that 11 per cent, or 1,050,000 acres, is put into farms; that 60 per cent, or 5,642,000 acres, is restocking with forest and can be counted upon, to a greater or less extent, for future timber supply; and that 29 per cent, or 2,737,000 acres, is not restocking and can be made of future value as timber-producing land only by artificial reforestation.

The annual growth of wood on all classes and types of forest land in the United States, including cut-over areas which are restocking, is estimated at 12 cubic feet, or 72 board feet, per acre. On this basis the original forests of the country, covering 900,000,000 acres, produced annually 64,800,000,000 board feet of timber, or enough to supply fully the annual consumption of lumber, cord wood, and every kind of forest product up to within the last ten years. On the same basis the annual growth of wood on the present forested area of the United States of 515,000,000 acres, including land bearing merchantable timber and cut-over areas which are restocking, is a little more than 37,000,000,000 feet, less than 58 per cent of the original production. Regardless, therefore, of the actual amount of timber which has been cut from year to year, the clearing of forest acres for agriculture and methods of logging which leave the cut-over land in such condition that natural reproduction is not possible have caused a loss of 25,704,000,000 board feet in the annual wood crop of the country. Of this amount a little over 21,000,000,000 feet is an unavoidable loss, resulting from the necessary increase in the area of farm land. There is, however, a present annual loss in the wood crop of the country of 4,680,000,000 board feet on the area of cut-over land which is not put into farms but which, because of the methods of logging employed and the lack of protection, is not restocking with forest. It has been shown, furthermore, that the farms are encroaching upon the forested areas at the rate of 1,050,000 acres a year and that the area of cut-over land which is not reforesting is increasing at the rate of 2,737,000 acres a year. In other words, the annual loss in growth resulting from the withdrawal of areas from timber production is increasing at the rate of 272,664,000 board feet a year. Of this increase in the yearly loss of growth, 75,600,000 feet may be classed as necessary, because it results from the increased acreage put under tillage; a loss of 197,064,000 feet, arising from the cut-over lands which are not put to any economic use and at the same time are not restocking with forest, should be classed as unnecessary, or national waste.

The significance of this steady decrease in the growing stock of the country lies in its cumulative effect upon future timber supplies. The loss in growth of timber on the areas which have been and are being withdrawn from forest production, either as farm land or as nonrestocking cut-over land, if the present rate of increase is maintained, will amount in ten years to 272,146,520,000 board feet. If the element of farm land is eliminated, the loss resulting from the unproductive cut-over lands alone will, in the same period, aggregate 57,638,520,000 board feet. In twenty years the loss from both sources will become 596,452,920,000 board feet, and from the unproductive cut-over lands alone 124,144,920,000 board feet.

The greatest and most permanent factor in reducing the annual growth and future supply of timber in the United States has been the necessary clearing of forest-producing lands for cultivation. It is therefore pertinent to inquire what limits, if any, can be placed upon the increase in improved farm land and the proportionate decrease in forest-producing land. So many factors enter into this question—the future increase in population, the extent of agricultural exports in the future, the probable increase in the average production per acre, the probable decrease in the consumption per capita—that there is little reliable basis for even approximate estimates. It will be attempted simply to indicate the present trend as to the increase in the crop-producing area and to suggest its future limits if certain broad assumptions are accepted.

Table V has been prepared to furnish a basis of comparison between the increase in population in the United States from decade to decade and the accompanying increase in the acreage, production, and home consumption of the staple grains.

TABLE V.—*The population of the United States, by decades, compared with the acreage, yield, and home consumption of the staple grains—wheat, corn, oats, rye, barley, buckwheat.*

Year.	Total crop.	Exports.	Home consumption.	Area required for total crop.	Area required for home consumption.	Population.

1907	4,180,303,000	454,622,632	3,727,680,368	186,153,000	163,718,365	85,000,000

NOTE.—The crop, export, consumption, and acreage statistics in this table were compiled from the following publications of the Department of Agriculture: Agricultural Statistics, 1907 (reprinted from "Yearbook of Department of Agriculture for 1907"); Bulletin No. 55, Meat Supply and Surplus; Bulletin No. 34, Agricultural Exports of the United States, 1851–1902.

The population for the years 1850 to 1900, inclusive, is taken from the census reports. The population for 1907 is estimated.

The exports include flour, oatmeal, corn meal, bran, and middlings, and the estimated amount of grain consumed in producing the meat and meat products which are exported. This was arrived at as follows: The total exports of meat and meat products, live animals being reduced to dressed weight, were approximately 1,474,000,000 pounds in 1880, 1,612,600,000 pounds in 1890, 2,433,035,000 pounds in 1900, and 2,244,422,580 pounds in 1907. The ratio of 1 bushel of corn per each 11 pounds of meat was applied to these figures and the results included in the total grain exports of the respective years.

The exports do not include breadstuffs and other manufactured articles, since exports of this character are largely offset by imports.

The area required for home consumption was determined by dividing the amount of each kind of grain consumed in the United States in each of the respective years by the average yield per acre for that year.

From the foregoing table it will be noted that in the twenty-seven years from 1881 to 1907, inclusive, the grain area of the United States required to support the home population, wholly exclusive of exports, increased at the rate of approximately 2,400,000 acres annually. During the same period the population of the country increased at the rate of almost 1,290,000 souls a year. In other words, 1.9 acres of grain are required to support each person in the United States and the grain area of the country must be increased by that amount for each person added to our population. If we assume that the population continues to increase, not at the same ratio as during the past twenty-seven years but at the same average number of persons per annum, a far more conservative estimate, the country in 1950 will contain 55,470,000 more people than at present. If we assume, further, that the same conditions as regards average grain production per acre and average consumption per capita which have obtained during the last twenty-seven years will hold true until 1950, the country will require by that year an additional grain area for home consumption only of 82,958,000 acres. The grain area, however, forms but 41 per cent of the total acreage required for all agricultural products. If this ratio still holds, the total increase in improved farm land required for home consumption only by 1950 will reach 202,336,000 acres.

Outside of the areas of the United States, which were originally forested and which are coincident with the regions of abundant rains, expansion in the acreage of farm land is limited by water supply available for irrigation and by the areas susceptible of dry farming. The Reclamation Service estimates the total irrigable area in the West at 60,000,000 acres. No exact limits can be placed upon the area which sooner or later will be brought under tillage through the development of dry farming. It is probable, however, in view of the customary, if not essential, practice of fallowing the land in alternate years, that the crop-producing area added in any one year under dry farming will not exceed 40,000,000 acres. After making these allowances to cover the land which may be brought into cultivation outside of the forested regions, it is evident, under the assumptions above stated, that not less than 100,000,000 acres of forest must be withdrawn from timber production by 1950 in order to provide a sufficient food producing area to make the nation self-supporting.

It has been shown that of the original forested area in the United States 65,000,000 acres are completely cut over and are not restocking with timber and that this area is increasing annually at the rate of 2,737,000 acres. If this rate of increase is maintained until 1950, the unproductive cut-over land will in that year amount to 182,000,000 acres. With the further withdrawal of 100,000,000 acres from the timber-growing area required by the demand for agricultural crops, the acreage of forest-producing land of all classes will by 1950 be reduced to 298,000,000 acres, or about one-third of its original extent.

In any attempt to forecast conditions, the present bases of estimate or comparison are untrustworthy. It will be of greater value simply to indicate corresponding conditions in the older and much more thickly settled countries of Europe. Table VI shows the essential statistics of population, grain area, yield, and consumption in the United States compared with several European countries.

TABLE VI.—*Density of population, area in grain per square mile, average yield, and per capita consumption in the United States, compared with the most densely populated countries of Europe.*

Country.	Population per square mile.	Acres in grain per square mile.	Acres in grain per square mile required for home consumption.	Average yield per acre.	Annual consumption per capita.

NOTE.—The statistics for the United States are for the year 1907 and compiled from Table V. The statistics for the European countries are for the year 1905 and compiled from Bulletin 68 of the Department of Agriculture, entitled "Cereal Production of Europe." The grain area per square mile required for home consumption includes net imports, reduced to an acreage basis by dividing the imports of each kind of grain by the average yield per acre of the same grain in the respective countries. In the average yield per acre the net imports, reduced to an acreage basis as above, are included, the aim being to show as closely as possible the grain area required if each country were self-supporting. In the European statistics, exports and imports of meat or manufactured food products are not considered. Maslin, spelt, millet, and einkorn are included in the statistics for the countries where these grains are grown.

If the United States, for example, should ever attain a density of population equal to that in France, which in this country would mean a total of 571,000,000 souls, and should at the same time bring its average consumption per capita down to the French basis, we would require a grain area of 523,000,000 acres. In France, grain forms 53 per cent of the total area under cultivation. On that basis we would require, therefore, a total area in farms of 986,000,000 acres.

If the density of population became as great as in Germany, Italy, Denmark, or the United Kingdom, as indicated in the foregoing table, a still greater area under tillage would be required.

To make a second and less extreme comparison: Europe as a whole, with its seacoast, forested mountains, and great interior steppes, corresponds in a general way with the physiographic conditions in the United States. If this country attained a density of population equal to that of Europe as a whole, it would contain 103 persons to the square mile, or a total of 306,000,000.

Let us assume, further, that the average production of grain per acre is increased meanwhile from its present figure of 22.45 bushels to 29 bushels and that the consumption per capita remains unchanged. One and a half acres of grain would then be required for each person in the United States, or a total grain area of 459,000,000 acres. An approximately equal area would be required for other agricultural products, making the total area under tillage 918,000,000 acres. On the other hand, the preceding table indicates very clearly that if the production per acre were brought up to the highest level reached in Europe—namely, in Germany or the United Kingdom—and the consumption per capita reduced to the figures which now obtain in any of the European countries specified, except Denmark, a population of 300,000,000 could be amply supported by the United States with no increase in its present area of improved farm land. The indications are conclusive, however, that such changes will take place very slowly, and that as far ahead as can now be foreseen this country must face a steady reduction in its forest area to meet the insistent demand for agricultural land.

UTILIZATION OF WOOD WASTE BY CHEMICAL AND OTHER MEANS.

By H. S. Bristol and L. F. Hawley,
United States Forest Service.

The term "wood waste" as employed in this article includes discarded or unutilized wood or wood products which are depreciating in value through natural processes of decay, etc., which are being destroyed in order to get them out of the way, or which are simply unrecovered by-products.

CLASSIFICATION AND POSSIBLE USES OF WASTE.

Wood waste may be classified under three heads: (1) Natural waste, (2) primary waste, and (3) secondary waste.

Under (1) may be placed that waste which occurs as the result of the natural death and decay of mature, uncut trees. Such waste may consist of species of little value for which no extensive uses have been found, or valuable species which for various reasons can not be profitably handled.

Under (2) may be classified those materials which are discarded in the process of manufacture but still remain wood in some form, even though greatly altered mechanically. Such a waste includes that portion of the tree discarded in logging and sawmill operations, building and workshop refuse, etc., and may be further subdivided according to the particular form in which it occurs, as tops, stumps, butts, cull logs, slabs, edgings and trimmings bark, sawdust, shavings, etc.

Under (3) may be classified all forms of waste wood products which occur as a result of complete chemical alteration of the wood or which are by-products of ordinary methods of treating lumber; as sulphite liquor from pulp mills, pyroligneous acid from southern pine distillation, and turpentine from dry kilns.

In any young country richly endowed with forest lands wastes of the above nature invariably appear. As a rule the trees are cut for some special purpose, such as lumber, and it is impossible to utilize every portion of the tree in the production of this particular material. Until profitable uses are found for all parts, these wastes are bound to occur and are, to a certain extent, excusable. When, however, profitable methods for the utilization of these discarded portions are discovered, or when improvements in the methods of cutting and sawing make it possible to avoid much of the waste, it is criminal not to put such methods and improvements into operation.

As the civilization of a country progresses, its people develop new requirements and demand new and more expensive ways of gratifying them. In this manner new forms of wastes are often developed, although the new requirements may be to a certain extent satisfied by former waste materials.

The extent to which a country utilizes its waste may, in a sense, be taken as a measure of its development, and all the various factors which enter into the development of that country have an intimate bearing on the subject. Such utilization invariably starts locally, but, as progress is made, it takes on more and more national proportions. It is stimulated by many things, the most important of which are competition and the depletion of natural resources.

So long as the demand for the chief products of any industry exceeds the production, and profits are good, little thought is given to by-products. When, however, the industries have become thoroughly established, and competition in its various phases has become so great that the profits are reduced to a minimum, the eyes of the industrial firms are opened to the necessity of practicing the greatest possible economy. As competition of this nature increases, cheaper raw material and cheaper methods of production are provided, if possible; but it is generally the case that profits are more and more derived from the utilization of former waste materials.

Depletion of natural resources curtails production, forcing the people to seek substitutes, and very often waste materials are resorted to as substitutes for the chief products of the industry in which these wastes occur. For example, in many European countries where the forest resources have been greatly reduced, substitutes for lumber are commonly made from sawdust, a waste from the lumber industry.

Nor are competition and depleted resources the only factors which stimulate such forms of economy. With the country's development the desires and necessities of the people increase, and the number of commercial products increases, thus enlarging the opportunity for making substitutes. Such changes are bound to result in finding uses for new products and new uses for old ones. Then, too, the actual ability of the people to handle perplexing problems in a new country is only perfected gradually. The development of no two countries has ever been exactly the same, and the people very often have to be educated by experience to the point where they can solve their own particular problems, although a knowledge of the similar experience of other nations is generally of value.

Now, let us look at the other side of the subject:

There are many things which tend to retard waste utilization, even when there is a most pressing need for it. Among these may be mentioned:

1. Lack of demand for the products which may be obtained, or unfavorable economic conditions which make their production too costly.

2. Ignorance of the methods employed in other countries in which similar problems have arisen and of those employed in allied industries.

3. Prejudice in favor of a staple article which has long been used for a specific purpose, even though a new article may answer the

purpose as well as or even better than the old one, and lack of business organization to overcome this prejudice.

The advantages to be derived from utilizing waste are ordinarily looked upon by the individual from a standpoint of immediate gain to himself; the ultimate result, however, of such utilization is usually to increase not only the individual wealth by the amount of profit, but also the total wealth of the whole country by an even greater amount. And, further, unless the utilization of waste is put into effect as soon as it is found to be practicable, future development will be retarded by depleted natural resources.

The United States has now reached that stage in its development where it is face to face with a timber famine. The demands of the people are great, and the competition of the great industrial concerns to obtain control of natural resources (a most serious form of competition) is very keen. Such a condition of affairs should stimulate the large industries to adopt the far-sighted policy of practicing the strictest economy in the utilization of the raw materials under their control, but, strange to say, until recently very little attention has been given to the subject of the utilization of wood waste, and at present there seems to be a general lack of knowledge of the methods to be employed or the results to be obtained.

NATURAL WASTE.

It is impossible to obtain a close estimate of the annual amount of natural waste, and it will therefore be treated only in general. The waste which comes under this heading may be classified as follows: (1) Accessible timber which does not have a sufficiently high value for lumber to pay for extensive cutting; (2) timber which occurs in inaccessible localities; and (3), valuable decaying timber on lands held for future logging operations. The natural waste from only the first class might, however, be checked by new methods of utilization, and this class only will be discussed here.

Scrub pine in the East, and white fir, Engelmann spruce, lodgepole pine, and lowland fir in the West, are the principal species of this class. None of these trees has a high value for lumber, and the only one which was cut in sufficient quantity to be mentioned in the census report for 1907 was the white fir. The estimated stand of white fir in Oregon and California alone is 3,200,000,000 board feet, and considerable amounts also occur in northern Arizona and New Mexico. No estimates of the total amounts of standing Engelmann spruce are available, but over 1,500,000,000 board feet have been reported as occurring on four national forests. Scrub pine is said to form about 20 per cent of the wooded area of Maryland and 10 per cent of the wooded area of Virginia. The supply of lodgepole pine and lowland fir is also very large. None of these species are at the present time used to any appreciable extent and in some cases they greatly hinder the growth of more desirable woods.

A method for the utilization of this timber in such quantities as to make extensive cutting practicable would be of assistance in preventing much of the natural waste. Recent work of the Forest Service has shown that all of the species mentioned can be made into a commercial quality of paper pulp by the ordinary sulphite process.

The white fir and Engelmann spruce give especially good pulp, the product obtained from the former being even superior in some respects to that from the standard pulp wood—eastern spruce. In view of the facts that the price of pulp wood is steadily advancing and the demand for pulp and paper products is increasing, the possibility of utilizing this timber is very encouraging.

Another method which offers great possibilities in the prevention of natural waste by the utilization of certain species, which on account of their poor lasting qualities do not now possess a high commercial value—the method of preservative treatment—is discussed by another writer.

PRIMARY WASTE.

Species.	(1) Lumber produced in 1907.[a]	(2) Equivalent wood volume.[b]	(3) Total volume of logs.[c]	(4) Slabs, trimmings, and edgings.[d]
	Board feet.	*Cubic feet.*	*Cubic feet.*	*Cubic feet.*

All others	34,000,000	70,000,000	7,000,000	65,000,000	125,000,000

[a] Census reports for 1907.

[b] Obtained from the figures in column 1 by dividing by 12,000.

[c] Obtained from the figures in column 2 by dividing by 0.51.

[d] Obtained from the figures in column 3 by multiplying by 0.22.

[e] Obtained from the figures in column 4 by multiplying by 0.31.

[f] Obtained from the figures in column 3 by multiplying by 0.14.

[g] Obtained from the figures in column 6 by multiplying by 0.10.

[h] Obtained from the figures in column 3 by multiplying by 0.13.

[i] Obtained from the figures in column 3 by dividing by 4, the estimated ratio of tops to logs being 1:4.

This table was prepared largely from the estimates of Mr. Margolin on milling wastes in which the slabs, trimmings, edgings, etc., were given as 22 per cent, sawdust as 14 per cent, and bark as 13 per cent of the total log; the woods waste, including tops, stumps, and cull logs, was estimated as 20 per cent of the total tree. In making computations for the table, the above percentages, which are to be considered as averages for all species, were applied to each species separately, but the figures obtained are for all practical purposes sufficiently close to the actual total production of these by-products.

In collecting statistics, estimates were also obtained for the proportion of some of these products absolutely wasted. The reports from all the mills answering inquiries showed a total production of 1,873,246 cords of slabs, trimmings, edgings, etc., of which 469,511 cords, or 25 per cent, were burned for fuel at the mills; 822,526 cords, or 44 per cent, were sold as fuel, and the remainder, 581,209 cords, or 31 per cent, were burned in the refuse burners. By using 31 per cent as the absolute waste and applying this percentage to the figures for the total production of slabs given in column 4 the estimates of the absolute waste in slabs by species, given in column 5, is obtained. The absolute waste in sawdust is estimated from the same reports as about 10 per cent of the total production, about 90 per cent being used for fuel at the sawmill. Applying this 10 per cent to column 6 the absolute waste is obtained in column 7. No part of the bark is especially utilized as such except in a few species, although some of it is used as fuel in the form of sawdust or attached to the slabs. The woods waste shown in column 9 can be considered as all absolute waste, except in the case of very few species.

The possible uses for these wastes will be discussed according to special uses applicable only to certain species or groups of species, and general uses applicable to all species.

SPECIAL USES.

All woods containing turpentine in sufficient quantities can be utilized for the production of this material by the process of steam distillation. Reports indicate that southern yellow pine is the only timber whose sawmill waste could be utilized economically by this method under present conditions, although the wastes from Douglas fir and western yellow pine contain enough turpentine, so that it may some time be profitable to utilize them in this manner. The process consists, in brief, of treating the wood (chipped or "hogged" into small pieces, if not already in a state of fine division like sawdust) in a closed steel retort with steam under some pressure, and condensing the escaping vapors which consist of steam and the volatile oils from the wood. By this process the wood fiber is not injured, and the steamed chips can be used for fuel as well as before extraction. For this reason not only the absolute waste as given in columns 5 and 7 but also the amount of wastes burned as fuel at the mills, can be utilized in this manner. According to the estimates, 25 per cent of the slabs and edgings are used as fuel at the mill, and this added to the absolute waste, 31 per cent, will give the amount of slabs which could be treated by this process, 56 per cent, or, in the case of yellow pine, 266,000,000 cubic feet, or 3,325,000 cords. Practically all sawdust is either burned in the fire box or the refuse burner, or allowed to accumulate in the waste pile, the amount which finds other application being negligible. The total production of sawdust from yellow pine, 303,000,000 cubic feet, or 4,600,000 cords (70 cubic feet per cord) could, therefore, be utilized by steam distillation. There are also 540,000,000 cubic feet, or 6,000,000 cords of tops, stumps, etc., from this timber, making a total of 14,600,000 cords of waste wood which could be used for the production of turpentine. The average yield of turpentine from this material would be about 2.5 gallons per cord, giving 36,500,000 gallons of steam-distilled wood turpentine, an amount greater by 6,000,000 gallons than the total production of gum turpentine in 1905. Even at the extremely low price now current for this article, 30 cents per gallon, this would mean a product with a value of $10,950,000. On computing in the same way the waste from Douglas fir and western pine which might be utilized by this process, 5,200,000 cords of the former, and 1,660,000 cords of the latter are obtained. The average yields of turpentine from this material would be for Douglas fir about one-third gallon per cord and for western pine about three-fourths gallon per cord, giving a total of 3,000,000 gallons from these two woods.

The large-sized mill and logging wastes, such as slabs, tops, and stumps, from the three species mentioned could also be used by the process of destructive distillation for the production of turpentine, tar, tar oils, and charcoal, but such a method is more especially adapted to very resinous wood, such as old stumps and "light wood," and would probably not be profitable on the average mill and logging wastes unless the most resinous portions of these materials were selected. On account of the lack of estimates on the quantity of such material available, this process will not be discussed further.

Beech, birch, and maple were used by destructive distillation for the production of wood alcohol, acetate of lime, and charcoal to the extent of 1,220,000 cords in this country in 1907. Most of the wood is cut especially for this purpose, although the use of about 60,000 cords of sawmill slabs was reported in 1907. No practicable method has yet been found for the destructive distillation of small stuff, such as shavings and sawdust; so that only large-sized waste, such as slabs, ends, tops, and limbs, could be utilized by this method. The absolute waste in slabs, trimmings, tops, stumps, etc., from beech, birth, and maple, as given in the table, amounts to 1,115,000 cords (89,000,000 cubic feet), or over 90 per cent, of the amount of hard wood used for distillation in 1907. If this waste beech, birch, and maple had been utilized, products with a value of nearly $7,000,000 would have been obtained.

Oak wood is used to some slight extent in this industry, but only when mixed with beech, birch, and maple. Oak yields on distillation, in comparison with these woods, fully as much charcoal, nearly as much acetate of lime, and about one-half as much wood alcohol. There were wasted in 1907, 2,400,000 cords of oak wood, which, if distilled, would have produced very nearly twice as much charcoal and acetate of lime, and very nearly as much wood alcohol, as was produced in hard-wood distillation plants in this country during that year.

Hemlock, spruce, poplar, and cottonwood are at present being used in large quantities commercially as a raw material for paper making. Douglas fir, basswood, chestnut, and the various species of pine are used to a considerably smaller extent, but still can be and are successfully used for certain grades of paper.

It can be safely stated that almost any species of wood can be made into some grade of pulp, and that practically all species can be made to produce a pulp which is commercially acceptable. The economic utilization of waste wood is, however, a subject presenting some difficulties and requiring careful study. Waste wood is not in general the clear, clean wood to which pulp mills are accustomed, and often much trouble is experienced in preparing it for the digester; the knots, bark, rotten wood, and dirt must in many cases be removed, and the excessive handling in the preliminary treatment preceding the cooking process is often expensive. Waste wood of some species is, however, already being used with success (160,000 cords of slabs in 1907), especially where the pulp mills are located near sawmills. This method of utilization is therefore capable of great expansion. The utilizing of sawdust by this process has been little investigated up to the present time, but, according to some authorities, has possibilities. No final solution can at present be offered, however, and sawdust will therefore be left out of account in considering wastes that may be utilized for paper making.

If the slabs, ends, etc., which were absolute waste, and all the tops, limbs, etc., from the hemlock, spruce, poplar, and cottonwood cut for lumber in 1907 had been used for paper making, there would have been available, according to the table, 4,050,000 cords, or slightly more than the quantity of wood actually used for paper making in this country in that year. The use of yellow pine, Douglas fir, and western pine waste as mentioned does not prevent the use of the same material afterwards for paper making, since the wood fiber is not injured by the steam distillation. The only species which need be left out of the grand total which could be utilized for pulp are, therefore, beech, birch, maple, and oak, which have been considered as already utilized by destructive distillation. The total absolute waste in slabs is 450,000,000 cubic feet, or 5,600,000 cords, and in tops, stumps, etc., is 1,640,000,000 cubic feet, or 20,500,000 cords, giving a total waste of 26,100,000 cords. This amount minus 3,515,000 cords, the material already considered as utilized, leaves 22,600,000 cords, or five and one-half times as much wood as is annually used by the paper-pulp industry.

The only special use which has ever been found for large quantities of the bark of any species is as a source of tanning material. Hemlock and oak are the only barks which are now utilized for this purpose to a large extent, about 900,000 cords of the former and 380,000 cords of the latter being consumed in 1907. The total amount of hemlock bark produced as a result of the lumber cut in 1907 was, according to the table, 72,000,000 cubic feet, or about 900,000 cords, nearly all of which was utilized, since probably very little bark was cut without also using the lumber. The 380,000 cords of oak bark used in 1907 came mostly from the chestnut oak and the tanbark oak, since the bark from these species contains more tannin than from other oak. The total amount of bark from all species of oak cut for lumber in 1907 was 78,000,000 cubic feet, or about 970,000 cords, showing that about 590,000 cords of oak bark were unutilized. Oak wood also contains a small amount of tannin, but it is apparently not profitable at the present time to utilize this material or the bark from other oaks than tanbark and chestnut oak. In the year 1907 about 135,000,000 pounds of tanning extract from chestnut wood were used. If the absolute waste from chestnut, including all the sawdust, had been used in making tanning extract, 50,000,000 cubic feet, or 625,000 cords, of wood would have been available. At the rate of 500 pounds of extract per cord of wood this waste material would have yielded 312,500,000 pounds of extract, or more than twice as much as was used in this country in 1907. This does not indicate that half of this waste was actually utilized, because a considerable part of the extract was probably made from wood cut especially for this purpose. The use of chestnut wood for extract does not prevent the further utilization of the extracted chips for paper making, or of extracted sawdust for fuel. Other barks which contain tannin, which may be but are not utilized for production of tanning materials, are chestnut, willow, beech, birch, poplar, and spruce. Tanning materials worth $3,936,000 were imported into this country in 1907, which might have been replaced to some extent by domestic products manufactured from waste materials.

The possible profitable utilization of the leaves of conifers is apparently the last thing in the line of by-products to be thought of, and yet several years ago it was announced that the leaves of the eastern hemlock contained about 1 per cent of an oil which was composed of over 50 per cent borneol acetate, a substance which can be transformed into camphor by quite simple methods. More recently similar studies have been made on the leaves of the red cedar and Douglas fir of the Western States, with the result that volatile oils of possible commercial value have been obtained. There is a large field for investigation here, since the composition of the leaf oils of very few conifers is now known.

GENERAL USES.

In the above list of special uses there were mentioned possible methods for the utilization of all the large-sized waste, except the bark from those species which do not contain tannin in sufficient quantity to make its extraction profitable. No methods were suggested, however, for the complete utilization of the sawdust. The steam distillation of yellow pine sawdust, or the leaching of chestnut sawdust, still leaves the main woody material for further treatment. Under "General uses" will be mentioned in three divisions—(1) chemical, (2) mechanical, and (3) fuel and power—methods which are applicable to all species alike, and to sawdust as well as or even better than to larger sized material.

(1) Under general chemical methods of utilizing sawdust may be mentioned the production of oxalic acid by treating sawdust with fused caustic alkali, and the production of ethyl or grain alcohol by treating sawdust with dilute sulphuric acid and fermenting the sugar so formed. Practically no oxalic acid is manufactured in this country at present, and 7,900,000 pounds were imported in 1905.

This process is not of much interest, however, as a method of utilizing waste sawdust, because 8,000 tons of sawdust, or only about 0.05 per cent of the total sawdust produced in this country in 1907, would make as much oxalic acid as was imported in 1905.

It is well known that ethyl or grain alcohol can be produced from wood by the general method of hydrolysis by acids with subsequent fermentation of the sugar so formed, and processes for the commercial utilization of waste wood in this manner have often been suggested. One of these processes was tried in this country a few years ago, but resulted in a failure, apparently because of difficulties in the mechanical manipulations rather than in the control of the fundamental chemical reactions. A special modification of the general method is said to be in successful operation in France, and new modifications have lately been suggested in this country which it is claimed will make successful operation possible here. Different investigators have claimed to be able to produce from 15 to 30 gallons of alcohol per ton of sawdust; at even the lower figure 19,500,000 gallons could have been produced from the sawdust which was absolutely wasted in 1907. This method is, of course, also applicable to the other classes of waste besides sawdust, except possibly the bark.

(2) Sawdust has three marked mechanical or physical properties which give it a certain commercial value. It is elastic, absorptive, and nonconducting. Various minor uses to which it has been put on account of these and other similar properties are here enumerated. These are uses applicable to the sawdust from all species.

Packing material.—The use of sawdust as a packing material for fragile articles for shipment is well known. Its value along this line is shown from the fact that it is used to pack dangerous explosives for transportation. When sawdust is well dried and free from dust, it can be used in contact with polished metal surfaces without rusting or tarnishing them.

Nonconductor.—The intermediate spaces between the joists in buildings may be filled with sawdust to make the walls more nearly "cold proof." The use of sawdust in packing ice to retard melting is well known. Sawdust with plaster of Paris or other suitable binder makes a very good material for covering steam pipes, etc., to prevent radiation of heat.

Absorbent.—Wood flour, or very finely-ground wood, is one of the best known absorbents for nitroglycerin in the manufacture of dynamite. This material is at present made in this country almost entirely from ordinary pulp wood, although in Europe it is made very largely by grinding sawdust. A large saving could be effected if this material were manufactured from a waste product, sawdust, instead of from pulp wood which could be used for other purposes. A common example of the absorptive power of sawdust is found in its use as a stable litter and in public conveyances, meat markets, etc., to keep the floors free from moisture. It also finds extensive employment in the metal industries for drying metallic articles which have been treated with acid, no other substance being so effective in drying and cleaning, and preventing subsequent oxidation such as the formation of rust or verdigris.

Porous brick.—If sawdust is mixed with the clay used in making bricks, it burns out during the treatment in the kiln and leaves the brick full of small cavities. These porous bricks are used instead of hollow tile in partition walls, and are claimed to be even better as a nonconductor. In the year 1900 sawdust to the value of $19,687 was used in the clay and pottery industry of the United States for this or for similar purposes.

Wood substitutes.—The utilization of sawdust as a wood substitute is ideal from the forest conservation point of view, since it makes use of a waste product of the lumber industry as a substitute for the principal product of the industry. There are many methods which have been proposed for manufacturing an artificial wood from sawdust, and some of these have been used on a commercial scale, but progress along this line has been carried further in England and France than in this country. The production of a wood substitute with the elasticity and strength of natural wood is not to be expected, but in moldings, carvings, flooring, paneling, etc., an artificial wood can be very readily substituted. The methods all consist in general of mixing the sawdust with some suitable binding material which hardens on drying or on heating, and then molding the mixture under pressure and heat, or making it into blocks or sheets as the various binders and the various requirements of the product call for. Water glass, glue, rosin, plaster of Paris, blood, casein, etc., and various mixtures of these materials are the binders used. A flooring material made of sawdust and Portland cement is used to a large extent in Germany in place of ordinary plank flooring. It is lighter and more elastic than cement alone, and gives a floor without cracks. A flooring or decking material similar to the above is found on the European markets. This material has been used on the lower and second-class cabin decks of many trans-Atlantic vessels with excellent results. Although materials of this kind have not been extensively used in this country, it is known that wood flour or finely ground sawdust has been used to some extent in flooring, such as linoleum substitutes, and its use as a substitute for the ground cork in linoleum itself has also been reported.

In these various applications of the peculiar physical properties of sawdust there are many possibilities for an expansion of its present use.

Fuel and power.—Probably the one largest use to which sawdust is put in this country is as fuel, but this is almost entirely confined to the immediate plant in which it is produced. Special fire boxes and grates are required, and it is never so satisfactory as larger-sized wood. It is also so bulky that its transportation away from the plant is not economical. It may be stated in this connection that the full fuel value of sawdust is seldom developed under present conditions, mainly because the mills burning it have a very plentiful supply and need not economize. If, therefore, it became necessary or profitable to economize in this respect, much less sawdust could be used with the same results. A method has been suggested for making sawdust more readily transportable and at the same time making it a more satisfactory fuel by pressing it with or without a binding material into briquettes. This method is not profitable in this country on account of the other cheap fuels nearly everywhere available, and on account of the cost of briquetting. As fuel becomes scarcer, however, this plan will become more practicable.

The method by which sawdust can be most economically transformed into power is probably by means of the gas producer and the gas engine, gas producers now being on the market which are claimed to make a gas as consistent in composition and as satisfactory for gas engines as any producer gas made from other materials. The possibilities for the transportation in the form of electrical energy of the power obtained from sawdust through the use of the gas producer and gas engine seem to be greater than for the transportation of the sawdust, either loose or in the form of briquettes.

SECONDARY WASTE.

In 1907, 2,059,496 cords of wood were made into paper pulp by the sulphite process. About 1,030,000 tons of pulp were made from this wood, the remainder, about half the total amount by weight, being left combined with the chemicals used in the form of "waste sulphite liquor." This substance has been investigated by many experimenters in an endeavor to find some method for its utilization. Its uses as a briquette binder, dust layer, sizing for paper, and tanning material have been suggested, but none of these methods have up to the present time attained any commercial prominence. The large amount of this waste material available, however, and the information which has already been obtained regarding its properties surely warrant further investigation.

Pyroligneous acid from pine-wood distillation.—In the year 1907, 61,149 cords of pine wood were distilled in the United States. Probably 45 per cent of this wood, 27,518 cords, was distilled by the destructive process, one of the products of which, pyroligneous acid, is almost entirely wasted. This pyroligneous acid contains wood alcohol and acetic acid, and if these two products were recovered the yield would be about 3 gallons of 82-per-cent alcohol and 50 pounds acetate of lime per cord of wood; 82,554 gallons of wood alcohol and 1,400,000 pounds of acetate of lime were therefore wasted in 1907. The recovery of the materials has never been successful on a commercial scale in this country, although in Germany they are considered valuable products of the process and are saved.

Turpentine from dry kilns.—Probably 30 per cent of the cut of yellow pine for 1907, or 3,964,555,000 board feet, was treated in dry kilns; probably 1 gallon of turpentine on an average was removed from every thousand feet so treated, and none of it was recovered; nearly 4,000,000 gallons were therefore wasted. A process of kiln drying has lately been proposed which claims to remove practically all the turpentine from resinous wood and at the same time to dry the wood quicker and better. If these claims are true there could be recovered probably 3 gallons of turpentine from every thousand feet of southern yellow-pine lumber dried, and there could have been produced in 1907 from the dry kilns an amount of turpentine more than one-third of the total production of gum turpentine in 1905. The complete removal of turpentine from the lumber of resinous woods improves the quality of the lumber, and rapid removal of turpentine vapors from dry kilns tends to reduce the fire risk. On account of these facts, it seems that a process for the recovery of turpentine from dry kilns can be made an economical proposition.

THE DIFFICULTIES.

In the necessarily limited amount of space occupied by the preceding chapters, it has been impossible to treat the subject with which we are dealing with all the detail which might be desired. The most that has been attempted has been to give approximations of the enormous quantity of annual waste, and to suggest some of the possible methods of utilizing it. In attempting to put any of these or other methods into effect, many difficulties are liable to arise, and any attempt here to classify these methods and point out the specific difficulties in employing each or the specific remedies for these difficulties would mean to occupy more time and space than can be had, and would further limit our view of the whole subject. At present it is necessary for a thorough understanding to obtain the broadest possible survey of the mighty task which this nation has before it. The chief difficulty seems to be a general lack of knowledge, not only of the materials to be saved and the products which can be derived from them, but of what has been done in foreign countries along these lines, and of industrial conditions at home—both local and national—which have a bearing on the subject. If more were known concerning the materials to be treated, it would be easier to suggest methods of utilization; if a better knowledge were had of the successes which had been achieved in foreign countries, and of the industrial conditions at home, it would be less difficult to pick out the methods most likely of success in this country. In a sense, there are already available many miscellaneous facts which are of great value, and it is possible to suggest at the outset methods, which, if employed, would lead to greatly improved conditions in the utilization of wood waste, but the employment of all these methods to their full economic value would save but a small portion of the vast quantity of waste. What is needed is more information. At present such as there may be is very scattered, and no one organization is in possession of all the facts or is making an extensive, systematic study of the subject.

In spite of the examples set by sister industries in the utilization of waste and the successes which have been reached, the subject of waste wood has in this country receives scant attention on the part of those immediately concerned. The reason seems to be that while prosperous business conditions prevail, private firms consider themselves too busy to make a careful study of the subject, and can see no immediate necessity for such an investigation; and in times of business depression they do not feel like making the necessary expenditure. In this connection it may also be stated that while the expense would not be greater than some corporations could readily afford, still for the great majority of firms a satisfactory investigation would greatly diminish the profits, and it is doubtful if the quantity of waste which the latter have at their disposal would be sufficient to warrant making the extensive investigation which might be necessary for a solution of the problem. Any investigation of this kind on the part of a small company is usually very limited in its scope instead of being a sound, scientific investigation of the whole subject. Further, industries which have already obtained a footing and might readily utilize wood waste with good profits under proper management remain for years in an unprogressive attitude toward this subject, when the proper application of capital and brains might lead to great developments.

HOW TO ATTACK THE PROBLEM.

First of all it is necessary to collect under one organization all of the available information bearing on the subject, both in this country and in foreign countries, and hold it in such form and place that it can be readily referred to at an instant's notice. This organization should keep in touch with all new developments along this line, and should not only distribute reliable information upon application, but should also actively bring to the attention of the proper persons the necessity of utilizing wood waste and the best methods to employ. Thorough cooperation should be had not only with the scientific men of the country, but also with the practical men of the industries. As many phases of the subject as possible should be studied at the same time, and in close cooperation with each other, and this could best be accomplished by having the work done entirely under one organization. Further, the spirit of this organization should continually be that expressed by the great French writer:

> The human race could increase its welfare almost as much by a better ordering of its consumption as by an increased production of wealth, and this without any retrenchment in consumption.

Certain classes of information can only be obtained by experimentation, and for this reason the organization should be provided with a thoroughly equipped laboratory for carrying on experimental work. The true value of many of the various processes could thus be shown, valuable old ones improved, and new ones suggested. Uses for new products and new uses for old ones could also be discovered, and infant industries in this way would be greatly aided. It may seem logical that the people who have waste wood to dispose of are the proper ones to undertake such experimental work and investigation, but there are many reasons why this is not so and why it is more advisable to have such work done by a central organization. Some of these reasons have already been expressed in the preceding chapter, and in addition it may be said that the results obtained from experiments of private firms would not be available for the use of others, and the good effects would therefore not be widespread. A government organization placed under the supervision of the Forest Service and provided with sufficient funds so that it could operate independently of cooperative money would be an ideal institution for carrying on this work. The ability of the Government to collect certain classes of information is greater than that of private firms, and there is an added advantage that the investigations would be known to be impartial and disinterested and would have the confidence of all concerned; and further, being under the Forest Service, which organization is constantly in touch with those most concerned, the work could be readily carried on in hearty cooperation with all interested parties. The solution of the problem will require time and patience and an organization of more or less permanence, but in the end the results obtained will amply justify a liberal expenditure.

In conclusion, it may be stated that the facts as already known firmly warrant further and more elaborate investigation, and it is earnestly hoped that in the near future an opportunity for making such an investigation will be forthcoming.

WOOD PRESERVATION.

By W. F. Sherfesee and H. F. Weiss,
United States Forest Service.

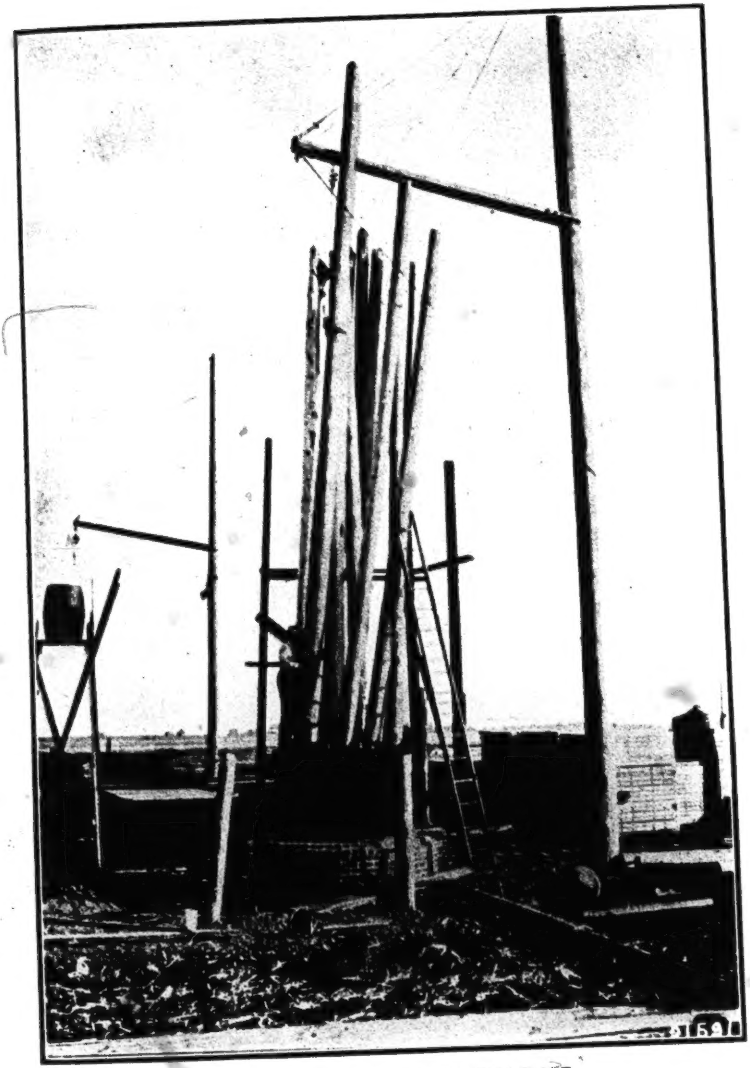
INTRODUCTION.

Wood preservation began in the United States on a commercial scale in 1848, when Mr. James B. Francis, C. E., established a kyanizing plant at Lowell, Mass. This plant is still in operation, although the amount of timber treated in it is comparatively small. About 1874 a creosote-impregnating plant was established at West Pascagoula, Miss. This was one of the first plants of its kind erected in this country and is still in active operation. Since then a number of others have been installed, the most rapid development being along the Gulf of Mexico. The gradual depletion of the timber supply, resulting in an increase in the price of the raw product, has more recently fostered the growth of wood-preserving plants, especially throughout the central and eastern United States. The ravages of shipworms have been primarily responsible for the installation of the plants on the Atlantic, Gulf, and Pacific coasts. In 1904 the total annual output of treated timber in the United States was approximately 500,000,000 feet b. m. In 1907 the number of plants had increased to 60, with a total annual output of approximately 1,250,000,000 feet b. m. New plants are being erected from time to time, and it is reasonable to expect that they will increase considerably in number and capacity.

Creosote is the most common preservative used, although a large amount of zinc chlorid is employed in the treatment of ties for the central western railroads. Experiments are now being carried on by the Santa Fe Railroad Company in treating ties with crude oil. If these prove successful the growth of wood preservation in the West will be very rapid. The high freight rates now existing in the Rocky Mountain States, coupled with the eastern localization of creosote production, have prevented a more rapid expansion of wood preservation in the West. The Forest Service is carrying on a number of experiments in which zinc chlorid is used in combination with crude petroleum. If these or similar experiments prove successful they will result in greatly alleviating this condition.

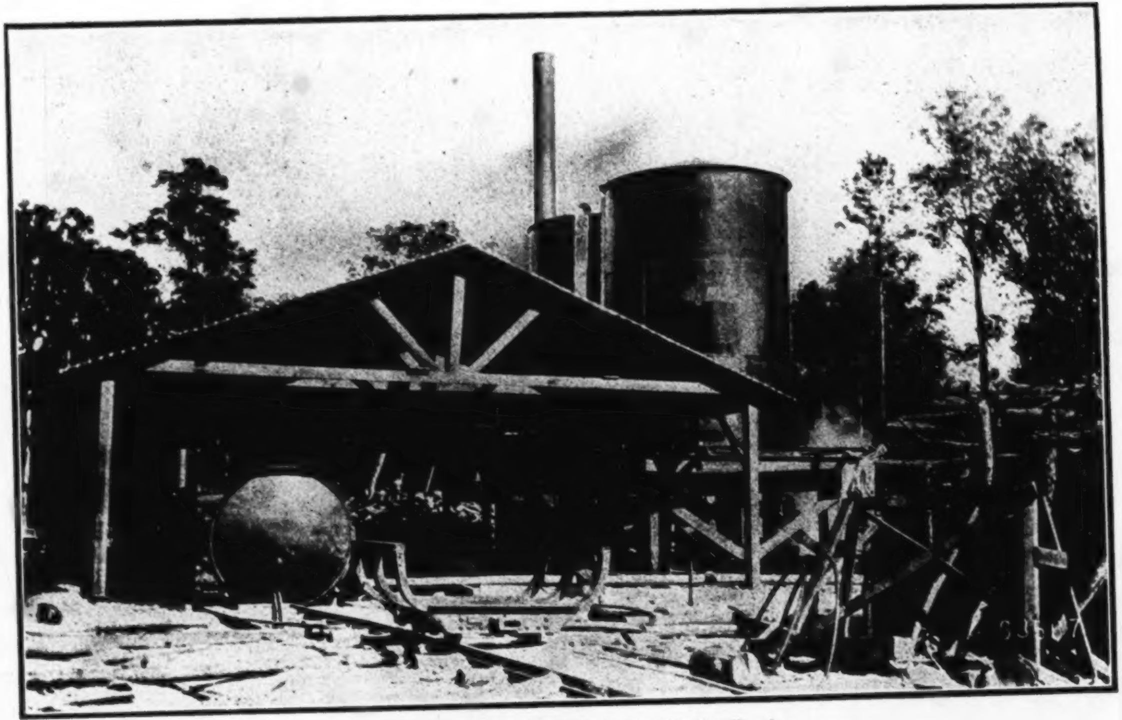
FACTORS INVOLVED IN THE PRESERVATION OF WOOD.

The preservative treatment of timber by chemical and mechanical means permits its more economical utilization by decreasing destruction due to decay, fire, marine borers, insects, and mechanical abrasion.



GENERAL VIEW OF TIMBER-TREATING PLANT.

(Partial submersion.)



GENERAL VIEW OF TIMBER-TREATING PLANT.

(Entire submersion of wood.)

Decay is by far the most serious agency, and affects most timber in contact with the atmosphere, soil, or water. Preservative methods are concerned, therefore, chiefly in protecting timber from this kind of destruction.

An enormous amount of timber is annually destroyed in the United States by fire. The fire loss in buildings in the United States amounts to about $251,000,000 per year. It is particularly desirable that this loss should be decreased, because it is usually accompanied by a corresponding loss of other commodities, and even of life itself. In the larger cities the substitution of materials for wood has tended to decrease the fire loss, but far greater protection can be rendered in the way of impregnating wooden floors, door casings, roofs, etc., with fire-resisting chemicals. Even if the chemicals do not succeed in absolutely checking the fire, its progress can be retarded to such an extent as to render difficult its gaining much headway.

The rapidity with which timber is destroyed by marine borers and the necessity for frequent replacements necessitates a large consumption for such purposes. The fact that thoroughly sound piling is often completely destroyed within a month shows the importance of protection and the wide field for its application. The activities of marine borers extend along both of our coast lines and as far north as Alaska. Next to decay and fire the destruction they cause is of the greatest importance in the preservation of timber.

Insects are responsible for the destruction of a large amount of cut timber each year in the United States. The loss is caused by their boring into the wood and thus fostering conditions for the growth and propagation of wood-destroying fungi.

The destruction of timber by abrasion is largely confined to railroad ties, fender piles, and mine props. The substitution of steel for wood in cars has very greatly decreased the loss due to this cause.

The following commodities should be given preservative treatment, which would result in a financial saving, as well as a more economic utilization of forest products: Railroad ties, poles, mine props, shingles, lumber, posts, and piling.

THE ANNUAL DESTRUCTION OF TIMBER DUE TO DECAY, FIRE, INSECTS, MARINE BORERS, AND MECHANICAL ABRASION.

This information can be best given by a compact table. Table I shows the estimated annual destruction of timber for each class of material adapted to preservative treatment according to each specific destructive agency. The figures are based on the same unit (b. m.) and are only approximations.

TABLE 1.—*Estimated annual destruction of cut timber in United States which can be eliminated or reduced by proper treatment (thousand feet b. m.)*

Class.	Total annual replacements.	Decay.		Fire.		Insects.		Marine borers.		Abrasion.	
		Amount.	Per cent.	Amount.	Per cent	Amount.	Per cent.	Amount.	Per cent.	Amount.	Per cent.
Ties	3,300,000	2,871,000	[a]87	....	....	16,500	½	....	....	412,500	12½
Poles	147,720	140,334	95	....	....	5,909	4	....	....	1,477	1
Posts	3,000,000	2,700,000	90	165,000	5½	120,000	4	....	....	15,000	½
Mine props	402,000	281,400	70	2,010	½	38,190	9½	....	....	80,400	20
Piles	191,520	9,576	5	....	....	....	....	181,944	95	....	....
Shingles	1,100	1,045	95	55	5	....	....	....	....	....	....
Lumber	2,625,000	1,863,750	71	131,250	5	315,000	12	52,500	2	262,500	10
Total	9,067,340	7,867,105	....	298,315	....	495,598	....	234,444	....	771,877	....

[a] This figure includes destruction due to fire as well as to decay.

The annual replacements of each class are found by dividing the total amount of timber in use by the estimated average life of the untreated timber.

EFFECT OF DETERIORATION IN THE QUALITY OF TIMBER UPON THE AMOUNT USED.

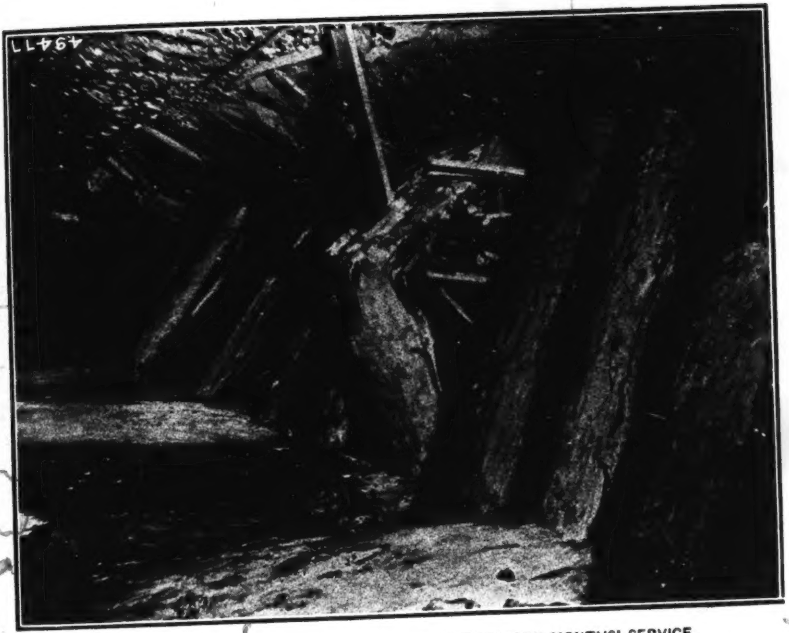
Table 1 shows the annual destruction of timber due to the five agencies mentioned. It is well known that the quality of timber is deteriorating each year, so much so, in many respects, that it has caused a complete revision of the specifications for grading it. This is due mostly to the exhaustion of the better grades, which has forced the utilization of the poorer qualities. Thus, where specifications once rigidly insisted upon first quality white oak for ties, or heart longleaf pine for dimension stuff, they are now given a very liberal interpretation, and species other than white oak are accepted with no difference in price, or considerable amounts of sapwood are allowed on "all-heart" sticks.

This deterioration in quality naturally results in a decreased length of life, which in turn compels a larger annual cut of timber. Hence, the amounts given in Table 1 will increase year by year in direct proportion to the decrease in quality.

HOW WOOD PRESERVATION WOULD LESSEN THE DRAIN ON THE FORESTS.

That the drain on the forests of the country would be materially reduced by a proper preservative treatment of all structural timbers can not be doubted. It is very evident that by prolonging the life of timber a given number of years the amount cut for replacements would be correspondingly reduced. Table 2 shows this very conclusively. It is seen that if all ties, poles, posts, piling, mine props, shingles, and structural lumber adapted to treatment were given a proper treatment an annual saving of about 6,000,000,000 feet b. m. would ensue.

It is a well-established fact that a proper preservative treatment will prolong the life of the decay-resisting species as well as that of an inferior grade. By applying this treatment, it is evident that a reduction in the annual cut for replacements will follow, but since



UNTREATED AND TREATED MINE PROPS AFTER EIGHTEEN MONTHS' SERVICE.

The untreated stick has been weakened by decay and broken.

the increase over the natural life is larger with inferior grades, better financial results will be obtained by their use. The different species of wood, such as cedar, cypress, white oak, etc., which are naturally resistant to decay, have in former years been used to a very great extent. In consequence of this quality, the supply of these species is very rapidly diminishing, and the consumers are of necessity turning their attention to other species formerly largely disregarded on account of their inability to resist decay. The increasing demand for loblolly pine in the South and the lodgepole pine and Engelmann spruce in the West are examples. If these species are used in an untreated condition, they will decay far more rapidly than the timber formerly employed, and a consequent increased annual cut will ensue. Hence, it is essential that they be given a preservative treatment.

To sum up, wood preservation not only prolongs the life of durable timbers, thus decreasing their annual consumption, but also permits the substitution of inferior species, whose use considerably reduces the drain upon the more valuable kinds.

TABLE 2.—*Estimated reduction in annual cut which would ensue from a proper preservative treatment of all timber.*

Class.	Estimated average life, in years.		Estimated annual replacement—all species.		Estimated saving in annual cut (actual quantity).	Board measure equivalent (1,000 feet b. m.).
	Untreated.	Treated.	Untreated.	Treated.		
Ties	7	17	100,000,000	41,200,000	58,800,000	1,940,000
Poles[a]	13	23½	2,462,000	1,380,000	1,082,000	64,920
Posts	8	22	500,000,000	180,000,000	320,000,000	1,900,000
Piles	3½	21½	1,140,000	190,000	950,000	159,600
Mine props	3	13	[b] 67,000,000	[b] 15,300,000	[b] 51,700,000	310,200
Shingles	18	32	[c] 1,100,000	[c] 625,000	[c] 475,000	475
Lumber	8	20	[c] 2,625,000,000	[c] 1,050,000,000	[c] 1,575,000,000	1,575,000
Total						5,950,195

[a] No allowance is made for the fact that the greater percentage of poles now being treated are of so-called "inferior species". When properly treated they will have their natural life increased by more than the general average of 10.25. Hence, by a greater use of these species, there will ensue a corresponding reduction in the annual cut.

[b] Cubic feet.

[c] Feet board measure.

HOW WOOD PRESERVATION WOULD PERMIT SIMPLER AND MORE PROFITABLE SYSTEMS OF FOREST MANAGEMENT.

It has been pointed out that wood preservation brings into use the inferior qualities of timber, thus decreasing the drain upon those species of greater value. It should be noted that these so-called "inferior species" are often rapid growers and prolific seeders. Moreover, as a rule, they possess the requisite adaptability to environment which enables them to persist through a wide range of conditions, even under unfavorable circumstances. Their rapid growth produces a larger volume of wood, and quicker and larger financial returns.

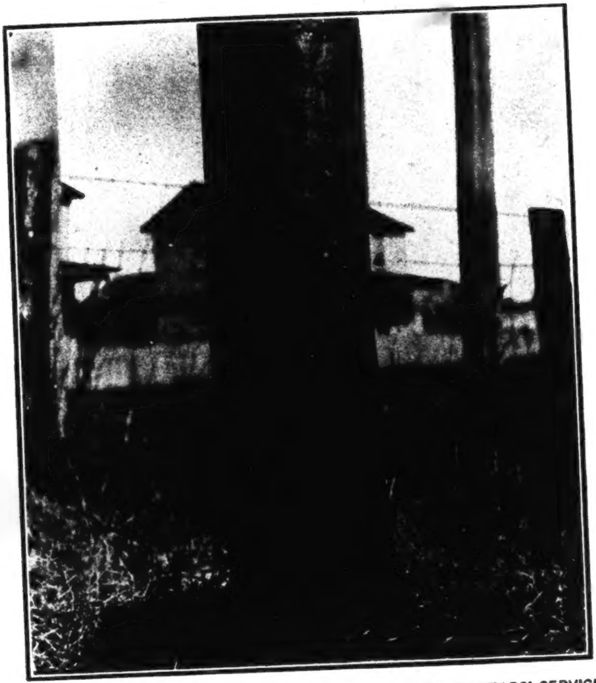
TABLE 3.—*Comparison of loblolly and longleaf pine from the standpoint of wood preservation and forest management.*

	Loblolly.	Longleaf.
Germinating percentage of seed	50 to 80	50 to 70.
Frequency of seed years	1 year	3 or 4 years.
Artificial reproduction	Easy	Hard to handle on account of long tap-root.
Natural reproduction	Good, because of its tolerance and rapid growth. It frequently comes in and drives out the longleaf. Lightness of seed allows wider distribution.	Poor because rare occurrence of seed years allows other species to get the lead. Its slow growth and intolerance cause it to be readily killed back.
Soil requirements	Will not grow in extremely dry soils. Prefers moister situations.	Less exacting; will grow on dry sandy soil.
Rate of growth	Very rapid. 12 inches diameter breast-high at 50 years.	Slow. 8 inches diameter breast-high at 50 years.
Yield per acre	Rotation, 70 years; diameter breast-high, 18 inches; yield, 33,000 feet b. m.	Rotation, 120 years; diameter breast-high, 18 inches; yield 25,000 feet b. m.
Cost of crops per acre (value land, $10;[a] taxes, 3 cents per year; fire protection, 2 cents per year; interest, 4 per cent).	$174	$1,244.
Estimated future value of crop per acre (loblolly, $8 per M board measure; longleaf, $13 per M board measure).	$264	$325.
Total profit or deficit	$90	$919.
Shipping weight, (pounds per M board measure).	3,000	3,500.
Adaptability to treatment	Adapted	Not adapted.

[a] Includes cost of reforesting.

It can be seen from Table 3 that the growth and cultivation of loblolly pine forests result in an annual profit of about $9 per acre more than for longleaf. It must not be construed, however, that this implies the total substitution of loblolly for longleaf, or, abstractly, the substitution of inferior for superior species. Sylvical factors often prevent this, but the fact remains that longleaf pine can not be grown at a financial profit under the conditions outlined in the table.

Many similar examples could be cited showing how a forest composed of the so-called "inferior species" would prove a better investment than one composed of the more valuable varieties. In other words, it is frequently better policy to cultivate rapid-growing trees for ties, posts, poles, piles, etc., and treat them, rather than grow those trees which are naturally durable and which take a long time to mature.



CREOSOTED YELLOW PINE POLE, SOUND AFTER EIGHTEEN YEARS' SERVICE.

INCREASED LIFE AFFORDED BY PROPER PRESERVATIVE TREATMENT.

The increased life afforded by proper preservative treatment is shown in detail for each class of material listed according to species in Tables 4 to 10, inclusive.

TABLE 4.—*Ties.*

Species.	Estimated average number years untreated life.	Estimated average number years treated life.	Species.	Estimated average number years untreated life.	Estimated average number years treated life.
Cedar	11	20	Post and burr oak	7	15
Cypress	10	20	Birch	5	15
Redwood	12	20	Beech	5	20
Chestnut	7½	15	Hemlock	5	15
White oak	8	20	Longleaf pine	7	20

CHESTNUT POLE, DECAYED AFTER SIX YEARS' SERVICE.

THE FINANCIAL SAVING RESULTING FROM THE PRESERVATION OF TIMBER.

The financial saving that would result each year in the United States, were a uniform policy of treating timber adopted, is shown for each class and in sum total in Table 11. The total annual saving would amount to about $72,000,000. It should be remembered that this includes the cost of labor as well as that of the timber itself, and thus represents the amount of money that could be turned each year into other channels.

THE SUBSTITUTION OF MATERIALS FOR WOOD.

In considering the substitution of materials for wood, the use of steel and concrete, both separately and in combination, has undoubtedly far exceeded that of all other materials. When one considers the vast quantity of reenforced concrete now used for all kinds of building and construction purposes, the amount of steel used for towers and poles in electric transmission lines, the number of steel and concrete piles and bridges, and the growing popularity of steel for the construction of railroad cars (which are only a few of the many ways in which these materials have been successfully utilized), it can be seen that the reduction upon the annual demand for structural timbers is considerable, and that the substitution of these and other materials is bound to increase from year to year. Engineers are continually experimenting with different materials with this end in view. Striking examples are the experiments being so widely carried on with steel and concrete railroad ties. Reports from 53 railroads show varied results with such ties during the past few years, but the fact that so many railroads are experimenting along these lines shows conclusively that the importance of the substitution of some material for wood is realized, and there is no reasonable doubt but that in the future some such substitution will be accomplished. Experiments that have been carried on with glass for use in poles are other examples of this tendency.

In substituting inorganic materials for wood, the limited supply of the materials must be kept in mind. Iron, for example, when once taken from the mine, is gone; it can not be renewed. Wood, on the other hand, is capable of growth, and hence of indefinite replenishment of supply from the same area. This fact will cause metals to rise in value, so that the ratio of cost between them and wood for construction purposes will be an ever changing one.

In the manufacture of coal cars, buildings, boats, etc., the substitution of metal for wood has passed the experimental stage. Uncertainly of successful substitution exists at present for ties, poles, piles, light cars and other vehicles, but the large number of experiments that are being carried on promise that here, too, in a large measure, wood will be supplanted. In 1904 the Carnegie Steel Company sold to the trade 11,329 steel railroad ties, and 572,233 in 1907. This company claims that the steel tie is no longer an experiment. The general impression throughout the country, however, is that considerable experimenting must be done before a satisfactory substitute for the wooden tie is found.

No estimate in figures can be given as to the effect the substitution of these and other less popular materials have or will have with regard to the reduction of the annual demand for structural timber. It is too vast for estimation, but it is important that substitutes be used wherever possible, since the available supply of timber is none too large to meet the requirements of industries which of necessity must utilize wood.

CONCLUSION.

Wood preservation began on a commercial scale in the United States in 1848. There are at the present time about 60 plants in operation, with a total output of approximately 1,250,000,000 feet b. m. Most of these plants are located in the South, East, and Central West, but the tendency will be to extend westward as the supply of timber gradually decreases.

The preservation of cut timber reduces its destruction by decay, fire, insects, marine borers, and mechanical abrasion. These factors destroy annually about 9,700,000,000 feet b. m. of cut timber in the United States. Decay is by far the most destructive agency; its retardation, therefore, is of prime importance.

On account of the rapid depletion of standing timber, grades of poor quality are now being sold in the market. This has resulted in more timber being cut each year to do the same work that a smaller amount of the better grades did a few years ago.

Wood preservation, then, accomplishes three great economic objects: (1) It prolongs the life of the durable species in use; (2) it prolongs the life of the inferior and cheaper woods; and (3) it permits the utilization of inferior woods which without preservative treatment would have little or no value.

Quite frequently inferior woods are rapid and prolific growers, and sprout up on cut or burned over areas in such numbers and with such persistence that the slower growing and the naturally more valuable kinds are hopelessly outstripped. Such restocked land has heretofore represented almost a total economic loss, because of the little value of the new crop. Wood preservation has changed this aspect. It has allowed these cheap woods to be utilized, and by so doing has decreased the call for skilled labor necessary to properly manage forests, and increased the revenue that can be derived therefrom.

Other things being equal, the increased life afforded by proper preservative treatment varies directly with the use to which the treated timber is put. Estimates on the increased life of various kinds and forms of timber are approximately as follows: Ties, 10 years; poles, 10¾ years; posts, 14 years; piles, 18 years; mine props, 10 years; shingles, 14 years; lumber, 12 years.

The increased length of life as a result of preservative treatment decreases the annual cut of timber in direct proportion to the increase secured. Table 2 shows that the total estimated saving would amount each year to approximately 6,000,000,000 feet b. m., or about 12 per cent of the total lumber cut. The saving of our timber resources, therefore, is strikingly apparent.

But still further, this saving in material wealth can be brought about by a corresponding financial saving in the cost of maintenance, thereby permitting current expenditures to be placed in other channels. In table 11 the total estimated saving that would accrue as a result of a uniform policy of wood preservation approximates $72,000,000 a year. This estimate includes timber set in position; hence the labor cost of placement is included. Thus it is not only possible to reduce the amount of lumber cut 12 per cent, but to do it at an annual saving of $72,000,000.

The substitution of materials for wood has met with greatest success in heavy construction. Steel and concrete are in most general use, and from the large number of experiments that are being carried on it seems reasonably certain that the field of successful substitution will gradually increase. This will result in very materially decreasing the drain on the forests, but just how much can not be predicted.

FOREST PLANTING.

By A. S. Peck,
United States Forest Service.

INTRODUCTION.

From reports received and compiled by the Forest Service it is estimated that 39,500,000 acres of the forest area of the United States must eventually be restocked by artificial means if this area is to be placed on the highest commercially productive basis. In addition, it is estimated that for the best interests of agriculture a total of 16,500,000 acres of naturally treeless land should be forested in the prairie region and on the irrigated land in the West, making a grand total of 56,000,000 acres. (See Tables 1 to 6.) A beginning in this work has scarcely been made, for the total area of planted timber in the United States amounts only to 962,927 acres, less than 2 per cent of what is needed.

For the purpose of discussing planting, the United States may be divided into an eastern, a central treeless, and a western region. (See fig. 1.)

EASTERN REGION.

This region includes all the country east of the prairie States, comprising the original hard-wood area of the East and the northern and southern coniferous forests. Of the two main purposes of forest planting, commercial and protective, the former is of chief importance in the East. This includes both the growing of timber and the production of material for special purposes. The classes of land which offer opportunities for planting are:

(1) Cut-over and burned-over lands, not fitted for agriculture, which are not restocking naturally with commercially valuable trees.

(2) Forest lands originally cleared for agriculture, which have since proven unsuitable for this purpose.

(3) Farm wood lots.

The most extensive areas of the first class consist of tracts of burned land in the spruce forests of the Northeast and the waste pine lands of the Lake States. Limited areas requiring reforestation occur in southern forests.

The most striking examples of the second class are to be found in the abandoned farms and waste lands of southern New England and the cleared lands of the southern Appalachians, damaged by erosion.

Throughout the hard-wood region generally, wood lots have deteriorated to such an extent that planting is necessary to restore them

● Location of planting plans, to July 1, 1908.

to their highest productive capacity. There are also tracts on many farms now lying idle or being cultivated at a small return, which are best suited for tree growth. These will aggregate a large area.

The total acreage of the eastern region requiring planting, 34,538,079 acres, is divided as follows: Northern forest, 17,853,279 acres; hard-wood forest, 11,532,600 acres; and southern forest, 5,152,200 acres.

The area of land upon which planting is necessary or may be practiced to advantage in the States included within the northern forest was computed from the actual area of cut-over lands, secured from the reports covering a certain percentage of each State, with the exception of Massachusetts, Rhode Island, and Connecticut. For the last State the state forester, Mr. Hawes's, estimate of 500,000 acres was used, and for the other two the area of waste land estimated by state officials.

The area of land requiring planting in the States included within the hard-wood forest was computed from the actual area of cut-over lands, secured from reports covering a certain percentage of each State, with the exception of Maryland, where the state forester, Mr. Besley's, estimate of 20,100 acres was used.

The figure given for the southern region does not include 12,000,000 acres not restocking at present in the Southern States, but on which it is considered adequate fire protection will insure natural reproduction.

The earliest plantations of the East were started by New England farmers, usually without any well-defined purpose other than an impression that the rapid removal of certain species must be met by planting. In recent years the purpose of planting has been more specific, including the production of special materials and the use of waste lands. The estimated acreage of plantations in the States included within the forest regions of the East is 93,111 acres.[a] This is divided among the three regions as follows: Northern forest, 43,346 acres; central hard-wood forest, 41,565 acres; and southern forest, 8,200 acres.

The federal and state governments have played a large part in the recent development of interest in planting, and the extent to which it will be practiced in the immediate future depends to a considerable extent upon the assistance and encouragement from these sources. In the past this help has been chiefly by advice and, to a limited degree, through distribution by several States of stock for planting. In the future it will be necessary for state governments to pay more attention to improving the system of taxation of forest lands and providing for adequate fire protection annually.

The Forest Service has, during the past eight years, prepared 181 plans for the planting of 42,687 acres of private lands in the East. (See fig. 2.) Many recent plans are for large areas, entailing planting annually for a series of years, and the acreage planted up to 1908 is a beginning only. Subsequent planting will increase this acreage much more rapidly. During the fiscal year ending June 30, 1908, 2,437 letters asking advice on planting were received from the eastern region and answered, and circulars dealing with the growing of the more important species were widely distributed. A total area of 3,304 acres planted thus far was reported July 1, 1908, as the result of advice given by the Service through planting plans and correspondence. In addition to this, experiments in nursery practice and planting are being conducted in cooperation with state institutions and forest commissions.

---

[a] These estimates are based on planting actually reported for a certain percentage of the area.

Eleven States have established nurseries under the supervision of state foresters, in which trees are grown for planting in state forests or for distribution among private landowners.

Forest planting will progress as the need of it becomes more generally felt and its practicability is demonstrated. Since planting requires a considerable initial investment and the cost is relatively higher than that required in inaugurating any other form of forest work, the most important factor governing its practicability is fire protection. Other controlling factors in its success are relatively cheap land, a good market for the class of products to be raised, lowest possible initial cost, and a low rate of taxation.

NORTHERN FOREST.

The northern forest offers the largest field for actual planting by States for commercial purposes and as an object lesson to private landowners. The principal state planting problems of magnitude are to be found in Michigan, Wisconsin, Minnesota, and New York. Except for planting on a limited scale for shelter and the restocking of farm wood lots in the various agricultural districts and the reforesting of abandoned farm lands in New England, planting on private lands will be done chiefly by large corporations. The chief opportunities for such planting are in the northern spruce region by lumber companies and in Pennsylvania by coal companies and railroads.

In the New England States, aside from extensive pitch-pine plantations on the sandy areas of the Cape territory of Massachusetts and the islands of Marthas Vineyard and Nantucket, as nearly as can be estimated on an acreage basis from the data at hand, over 90 per cent of the past planting has been done with white pine. Other conifers which have been noted as doing exceedingly well in particular cases are Norway spruce and European larch.

Examples of mature plantations of hard woods are comparatively rare. In experimental work in Connecticut the state forester finds that chestnut, red oak, locust, and sugar maple promise the best success as far as the experiments have been carried, but the plots have only been established a few years.

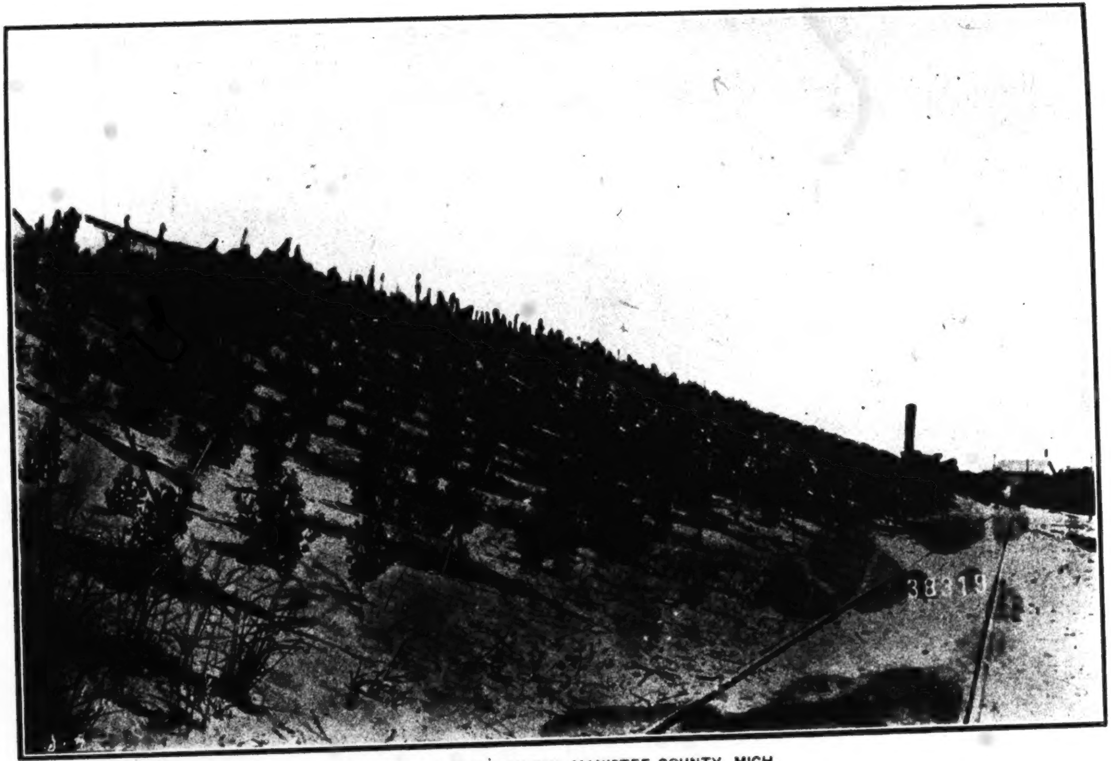
Planting has been chiefly for the following purposes:

1. Utilization of waste sandy areas unfit for cultivation. Over 10,000 acres of pitch pine were planted for this purpose in eastern Massachusetts; 150 acres in Narragansett Bay region.

2. Fixation of shifting sand. Three hundred and thirty-three acres have been planted to beach grass, bayberry, and pine at Provincetown by the Massachusetts harbor commission.

3. Utilization of cheap abandoned farm and pasture lands by wealthy owners as an investment and for improvement of estates.

4. By water companies to keep the supply clean and to produce wood of various sorts. The Metropolitan water board, Boston, has planted 1,100 acres on its watersheds.



SAND DUNE RECLAMATION, MANISTEE COUNTY, MICH.

5. By box-board companies, stave and heading manufacturers, to provide material for future manufacture.

6. By the State for experimental and educational purposes (Connecticut).

The Boston and Maine Railroad has set out 15 acres of white pine, principally for educational purposes. This company is also experimenting with hard woods in various parts of New England.

Past forest planting in the region has been of great economic importance, particularly in Massachusetts, Connecticut, and Rhode Island, in proving the practicability of forest planting for the utilization of sandy waste lands, abandoned farm lands, and for the production of box-board material.

Commercial companies have been aroused through a growing scarcity of timber. Those companies utilizing second-growth white pine began some ten years ago to increase their holdings of pine-wood lots varying in age from forty to sixty years; next they purchased thirty to forty year old stands; then lands having ten to thirty year old stands of pine; and within two years they have begun planting.

The practice of planting is decidedly on the increase, especially in Massachusetts, Connecticut, New Hampshire, and Vermont, but in Maine to a lesser degree. It is not on the increase in Rhode Island, but will undoubtedly be taken up when efficient fire protection and proper taxation are secured.

The progress by periods in Massachusetts has been estimated as follows: 1820–1880, 10,000 acres white pine planted;[a] 1880–1894, little planting done; 1894–1902, about 5,000 acres planted.[b]

During 1908 over 2,500 acres have been planted in New England.

Connecticut, Massachusetts, and Vermont distributed about 1,500,000 seedlings last year, which have not supplied the demand. One private firm disposed of 1,000,000 seedlings. Beginning in the spring of 1907 the state nursery of Vermont has since distributed or helped order perhaps 100,000 seedlings per year. This quantity, although relatively small, has been of quite disproportionately high educational value, since on account of it some fifty to one hundred other persons scattered over the State have made small trial plantations and have succeeded so well that they will continue the work. Almost every farmer in Vermont may wisely do a certain amount of planting under the direction of the state officials. The most hopeful places to begin the practice of forestry are the old, weedy back pastures which are now lying practically waste. Next to this is the filling in of blank spaces in natural stands. The farmer in Vermont will undoubtedly improve and plant his wood lot before the lumberman takes up planting to any great extent. It will, in fact, become a regular part of farm management.

White pine is considered the species surest of success. Red pine is of great value, especially for the drier soils, and the state experiment station is using Scotch pine on dry sands. Norway spruce is of especial promise for moist, strong land of the high mountain valleys—that is, all the natural spruce land. Small plantations of black locust are being tried for the purpose of producing posts and stakes.

In the immediate future State Forester Hawes believes that the greatest amount of planting in Connecticut will be done by wealthy owners as a side investment.

---

[a] Bulletin 45, The Planting of White Pine in New England, Bureau of Forestry.

[b] Estimate of H. B. Kempton, Woodland and Roadside, March 1, 1903.

In New Hampshire, Forester Ayres thinks that there will not be much planting purely for timber supply in the next few years, but that a great deal of planting will be done on a small scale as a part of farm management. There are several instances of plantations just started by manufacturing companies. One of these, a cooperage company, has planted 225 acres of white pine on a fifty to sixty year rotation, for stave and heading stock. Water companies in general are reported to be taking up a forest policy. In New Hampshire the species proving most suitable for planting are white pine and Norway or red pine for sandy soils and Norway spruce for loamy soils.

In Massachusetts wealthy land owners are doing considerable planting. State Forester Rane has distributed white ash (one-year seedlings) on a large scale throughout the State during 1907 and 1908. Experiments with this species so far in Connecticut have proven unsatisfactory.

In Connecticut the conifers best adapted for planting on the sand plains are Scotch pine, white pine, Norway pine, and pitch pine, and the hard woods which promise best are chestnut, red oak, locust, and sugar maple.

It is estimated that there could be harvested to-day from plantations in New England about: White pine, 5,000,000 feet b. m.; chestnut, 25,000 feet b. m.; locust, 4,000 feet b. m.; and other hard woods, 5,000 feet b. m.

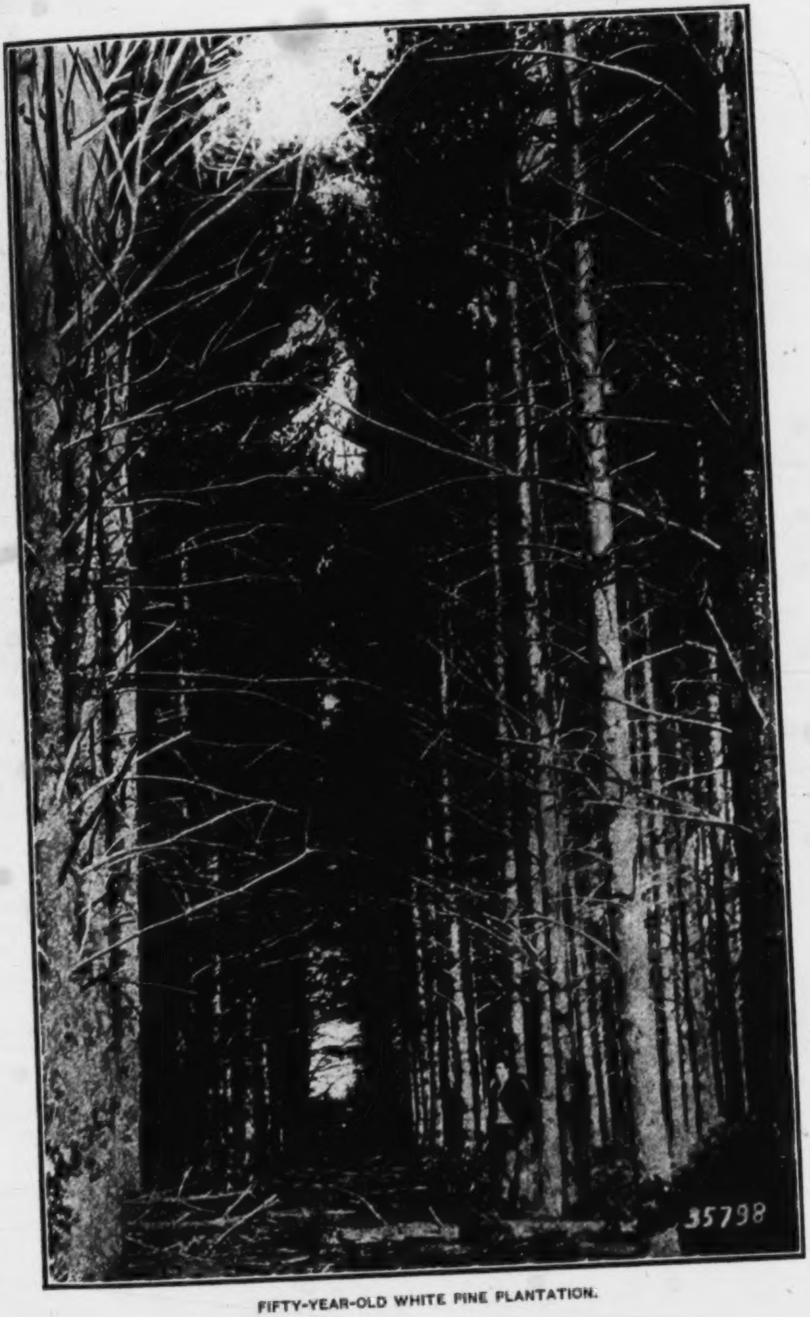
The great bulk of the plantations of white pine now in existence have been established within the last few years and will not be ready to harvest before 1930 at least. Something like 200,000,000 feet b. m. could be harvested between 1930 and 1950 from plantations already established if they are successfully maintained. Granting that one acre will yield 25,000 board feet at the end of forty years, all the stock planted in 1908, if successfully raised and harvested, in 1948 would yield 62,500,000 feet b. m.

The increasing field for forest planting in the New England States is indicated strikingly by the rapid decrease in recent years of the area of improved land in farms. This decreased from 11 per cent in Maine to 20 per cent in New Hampshire between the years 1890 and 1900, according to census figures. There are 2,500,000 acres in New England needing planting.

In New York State, aside from the restocking of forest lands in the mountain regions, forest planting is advisable for improving and renewing farmers' wood lots and making productive the waste areas on farms. The chief purpose of planting will be timber supply, and the species which are best adapted and which promise highest returns are white pine, red pine, Norway spruce, chestnut, red oak, basswood, tulip poplar, white ash, and in moist places Carolina poplar. The practice of planting is increasing rapidly. The work of the State in the Adirondacks is a remarkably fine example of good nursery practice and planting.

Pennsylvania divides readily into three sections where conditions of surface, soil, and climate are enough differentiated to modify the practice of tree planting in each.

The southeastern plains extend from tide water along the Delaware westward and northeastward along the Blue Mountains, which form



FIFTY-YEAR-OLD WHITE PINE PLANTATION.

the northern boundary of Cumberland, Lebanon, Berks, Lehigh, and Northampton counties. This was an early settled farming region, nearly every farm having its wood lot. Very few of these wood lots are in good condition, and in some cases this has caused the owners to become interested in forestry, and more or less tree planting has followed. The average prices of cordwood and fence posts and farm repair material generally are higher in this section than in any other portion of the State. This feature, coupled with the value of the land for agriculture, makes this region a splendid field for farm planting for quick-growing species that will produce in a comparatively short time fence posts and other timbers needed on the farm. More planting has thus far been done in this section of the State than in any other. The early purposes of planting were rather vague. Two classes of species were used—white pine, which was extensively planted and leads the class of slow growers, and the black locust, the most frequently planted of the rapid-growing species. No great degree of success has been attained, and the chief value of the early planting has been the creation of a general interest in tree planting among the people and the determining of the value of various species for planting. The great area of the near-by central mountain region, which is more valuable for tree growing than any other crop, makes it undesirable to devote these plains to other than rapid-growing species for the production of small-sized material.

Species which seem to give the best promise for planting are red oak, European larch, tulip poplar, and, where the wood can be given preservative treatment, cottonwood, silver maple, white willow, loblolly pine, and pitch pine. Catalpa has proven successful enough to justify its limited use on rich soils, and, with proper methods of growth, should prove a valuable post tree.

The central mountains comprise a broad belt extending from the northeastern part of the State southwestward to Maryland and West Virginia. This entire section was covered originally with splendid forests of pine, hemlock, and hard woods. The presence of unexcelled markets on the lake toward the north and along tide water toward the south will make the practice of forestry in this section as profitable as in any portion of the East. Excepting over the barren portions of watersheds that are supplying water for domestic use, there is no section of these central mountains in which extensive tree planting will be necessary, especially in view of the present inability of the owners, whether State or individuals, to protect their lands from fire. While the danger from annual or periodical fires is as great as now, it will not be a profitable thing to attempt to increase the value of these forests by general planting. As soon as the fire danger is diminished, natural reproduction will undoubtedly restore a forest cover that would compare well in density and composition with the original forest and should be supplemented by planting. In the central mountains the planting should be of white pine and spruce, and hardwoods such as red and scarlet oaks, tulip poplar, white ash, and basswood.

The western hills comprise a section in the northwestern part of the State extending from the Allegheny River westward to the Ohio line and Lake Erie. This section ranks next to the southeastern plains in agricultural value, yet contains a much larger amount of land adapted to tree planting in proportion to the total area.

The practice of planting would undoubtedly add materially to the general value of both farm and forest areas. Since there are considerable areas of essentially nonagricultural land separating the agricultural sections, slower growing species for the production of large timbers could be used profitably, while, as on the southeastern plains, quick-growing species may be planted to advantage on many of the farms. Thus far very little planting has been done in this section. In the western hills the soil is admirably adapted to white pine, European larch, and such hardwoods as red, yellow, and scarlet oaks, white ash, basswood, honey locust, and such rapid-growing species as cottonwood, soft maple, and white willow.

In the Lake States the practice of planting is increasing rapidly. They are divided into a southern hard wood forest and northern coniferous forest. The principal species planted have been white pine, Scotch pine, Norway pine, European larch, and, to some extent, the more rapid growing hardwoods such as locust, catalpa, black walnut, cottonwood, ash, and elm. In these States, where there is the greatest field for reforestation of cut-over lands, the united work of private individuals and of the state governments in reforesting nearly 13,000,000 acres will mean the rebuilding within seventy-five years of the lumber industry, which at its period of greatest activity produced nearly 40 per cent of the total cut in the United States.

CENTRAL HARD-WOOD FOREST.

In the States included within the hard-wood forest, planting will be done by farmers, to a limited extent, for protection from winds and to check erosion, but chiefly for the utilization of waste lands on farms; by mining companies, railroads, and manufacturers on nonagricultural lands for the production of pulp wood, box boards, mine props, ties, piles, posts, etc. The work of the various state governments in this region will be largely confined to assistance and encouragement of planting by various means, such as the distribution of publications containing advice and information, distribution of stock from state nurseries, and the conducting of forest work on state reserves, which will serve as an object lesson to private landowners. Such reserves on which planting is already being done are owned by Connecticut, Indiana, Michigan, New Jersey, New York, and Pennsylvania.

In New Jersey the principal species which have been planted in the past are white pine, Scotch pine, white ash, and white elm for purposes of timber production. The practice of planting is increasing greatly. It is, however, considered by the forester of the state forest park reservation commission to be relatively unimportant, and necessary only on abandoned fields. The species which give the best promise are the most rapid growing of the conifers.

In the central valley States the species chiefly planted have been as follows: West Virginia and southwestern Pennsylvania, walnut, locust, sugar maple, red oak, chestnut, and catalpa for posts, mine props, and timber; Ohio, black locust and catalpa for posts; Indiana, black locust, catalpa, and walnut; Kentucky, black locust, catalpa, tulip poplar, maple, and walnut, principally for mining timbers and posts; Tennessee, locust, maple, and cedar; Missouri, catalpa, locust, walnut osage orange, cottonwood; and Arkansas, locust and walnut.

20-YEAR-OLD BLACK WALNUT PLANTATION FROM SEED, TIPPECANOE COUNTY, IND.

SOUTHERN FOREST.

In the southern forest region the artificial restocking of denuded areas will be almost wholly the concern of lumber companies and other large landholding corporations and will consist chiefly of seeding with native pines to supplement the protection and management of forest lands, which for the most part are reproducing naturally.

Of the total area of cut-over forest land which is not restocking naturally, it is estimated that probably 70 per cent will reproduce well to pine if protected from fire for a long enough period. Thirty per cent, or 5,152,200 acres, is therefore given as the area requiring artificial restocking. While most of this area lies within the southern pine forest, there are limited opportunities for planting in the Appalachian Mountain region and in the northern portions of Georgia, Alabama, and Mississippi. Planting thus far has been almost altogether of rapid-growing hard woods, such as catalpa, and was for the most part ill advised. It serves as no indication at all of the lines along which planting will progress in the future. The hardy catalpa is practically unsuited for planting in any portion of this region. For quick production of material in small sizes, black locust is especially well adapted for the mountain and Piedmont sections of Georgia. The white oak is well adapted for planting in Georgia for the production of posts, ties, etc. For post production it will, however, probably prove most profitable to grow loblolly pine and treat it with preservatives. Carolina poplar grows rapidly in the South and makes good chemical pulp. The practicability of planting this, however, is somewhat in doubt, since it has been found that pine can be used for pulp.

In general, it may be said throughout this region that planting is unnecessary, since reproduction of the longleaf and loblolly pines is abundant wherever cut-over forest lands or abandoned farm lands are protected from fire.

CENTRAL TREELESS REGION.

The area included within this region comprises the States of Illinois, Iowa, North Dakota, South Dakota, Nebraska, and Kansas, the prairie district of Minnesota, and the portions of Oklahoma and Texas lying west of the hard-wood belt.

Tree planting in this region was begun on a considerable scale some thirty or forty years ago, to provide shelter from the heavy winds. In extent of past planting, it is the most important region of the United States.

An effort was made to stimulate interest in planting on the western prairies and plains in the years 1873–74 by the passage of timber-culture acts. Many tree claims were started in the treeless region under these acts, but owing to the crude provisions of the law and the lack of knowledge regarding planting on the part of the homesteaders, the securing of much land by fraudulent means resulted and the planting accomplished has in the aggregate been of relatively small value. The law was repealed in 1891.

Planting has followed the progress of agriculture, and has been most extensive in the region of best agricultural development. Nebraska and Kansas lead in the acreage of plantations. Assessors' figures compiled in 1904 indicate that Nebraska had 286,000 acres of planted timber at that time, and it was claimed that Kansas had 142,984 acres of plantations in 1900. The area of private forest planting of which there is record in all the States included within this region is 752,443 acres. The total estimated area of past planting is 830,954. That which should be devoted to this purpose is estimated to be in the aggregate nearly 15,000,000 acres.

In early planting for protection, the tendency was to make use of rapid-growing species which could be obtained cheaply, without regard to their final commercial value in plantations. Owing to poor selection of species, indiscriminate planting on sites not suitable for the species used, and ignorance of proper methods, much of this early planting has given very poor results. As a result, however, of the very large extent to which planting has been done under widely diverse conditions, the problems of this region are fairly well solved and the lines of future development clearly indicated. Sufficient success has been attained to demonstrate that, with a right choice of species and methods, forest planting for commercial purposes is practicable.

As in the past, planting in this region will be almost entirely a private enterprise, carried on in connection with farming. While protection is and will be in general the primary object, planting will be done from the commercial standpoint, since by using only profitable species it will easily be possible to secure the advantages of shelter and ornament, and at the same time derive a revenue from all the plantations.

Until quite recently planting was for a number of years on the decline or at a standstill in the older farming regions of Illinois, Iowa, Nebraska, and Kansas. The cutting of mature plantations offset in acreage what new planting was being done. As might be expected, the planting of shelter belts is greatly on the increase in the newer farming districts of the Dakotas and Oklahoma, and, owing to the increasing evidences of the value of plantations, interest in planting is again being revived throughout the region. The following figures, giving the comparative distribution of stock for the past three years, by forty-five of the principal commercial nurseries which handle forest-tree seedlings, show the increase of interest, since the greater portion of this stock was sold for planting in the prairie region: 1906, 24,530,929; 1907, 38,540,202; and 1908, 40,791,193. Of these trees, 70 per cent were hard woods and 30 per cent conifers.

The advantages and the necessity in most cases of having a certain proportion of the land in agricultural districts under forest cover have been clearly demonstrated, and it is considered that 5 per cent of the prairie region should be forested for the best interests of agriculture. Farther west on the plains, 3 per cent of the land may very well be devoted to tree growing. The ninety-ninth meridian is arbitrarily used as the dividing line, 5 per cent being used for States or parts of States east of this meridian and 3 per cent west. Figures on the area of land that should be planted are obtained by subtracting the area of land already planted from 5 per cent or 3 per cent of the total area, according to the location of the State.

PLANTATION OF HARDY CATALPA, KANSAS.

27-YEAR-OLD EUROPEAN LARCH PLANTATION, ILLINOIS.

Figuring on this basis and that of the acreage already forested, there remains 14,160,246 acres on which planting is very desirable and may be done to good advantage. In addition to this there are about 653,352 acres of grass land in the sand-hill district of western Kansas and Nebraska, now under the control of the Federal Government, as much as possible of which it is intended to forest for the production of commercial timber and as an object lesson to the people of the region.

Owing to the fact that the opportunities for tree planting and the practicability of it became earliest apparent in the treeless States, the first efforts of the Forest Service for the encouragement of planting were directed toward this region. Since 1899, 223 planting plans have been made for private landowners, covering a total acreage of 5,488. (See fig. 2.) During the fiscal year ending June 30, 1908, 1,129 letters asking for advice on planting were received from this region and answered, and there has been a wide distribution of circulars dealing with the results of careful studies which the Service has made of the districts most important from the tree-planting standpoint. Up to July 1, 1908, a total area of 1,072 acres has been reported planted as the result of advice given by the Service by planting plans and correspondence. Experiments to determine the value of various species and methods are being conducted in cooperation with the States of North Dakota, Nebraska, and Iowa.

All of the States in this region have taken more or less interest in forest planting. Minnesota expends $20,000 annually in bounties for tree planting in the prairie sections of the State. Kansas maintains a state nursery, from which trees are distributed to private landowners, and experimental planting is being conducted by state institutions in six of the States. Owing to the nature of the planting problems in this region, the future action by States will be wholly along the line of demonstrating to private landowners the practicability of planting and the best methods.

ILLINOIS.

Although the southern portion of this State is properly included within the central hard-wood region, it is considered a prairie State. Seventy per cent of the total area was reported upon by county clerks; 10,898 acres of planted timber were reported, making the estimated total of past planting 15,568 acres. The area upon which planting is desirable is 1,456,526 acres. According to reports received, the practice of planting is waning. The species chiefly used in the past were black walnut and hardy catalpa, and the chief purposes were for shelter belts, for production of posts, and for fuel.

IOWA.

Prof. C. A. Scott estimates the area of past planting to be 125,000 acres. While this figure is considerably more than that reported by county clerks, it seems reasonable, and was used. The area upon which planting is desirable is 1,929,752 acres. Planting is reported to be decidedly on the decline. The species reported to have been planted chiefly are, in the order of their predominance, silver maple, black walnut, cottonwood, boxelder, willow, ash, elm, and catalpa. Shelter ranks first among the purposes of planting, with fuel, posts, and timber supply next in order.

MINNESOTA.

The western and southern prairie portions are included in this region. The total amount of past planting, as estimated by General Andrews, state forest fire warden, is 115,000 acres. The area of land which should be planted is 1,178,728 acres. The practice of planting is reported to be slightly on the increase. The species which are most commonly planted are boxelder, cottonwood, maple, willow, ash, and elm, for purposes of timber production, shelter, and fuel.

NORTH DAKOTA.

An area of 44,746 acres of planted timber was reported from 86 per cent of the area of the State. The total area of past planting is estimated at 52,030 acres. The area upon which planting should be done is 1,578,000 acres. Three per cent of the area of irrigation projects in this State (2,280 acres) is also included in the total to be planted. Planting over the entire State is reported to be increasing rapidly. The species chiefly used are boxelder, cottonwood, green ash, and willow, and the chief purposes of planting are for shelter and post production.

SOUTH DAKOTA.

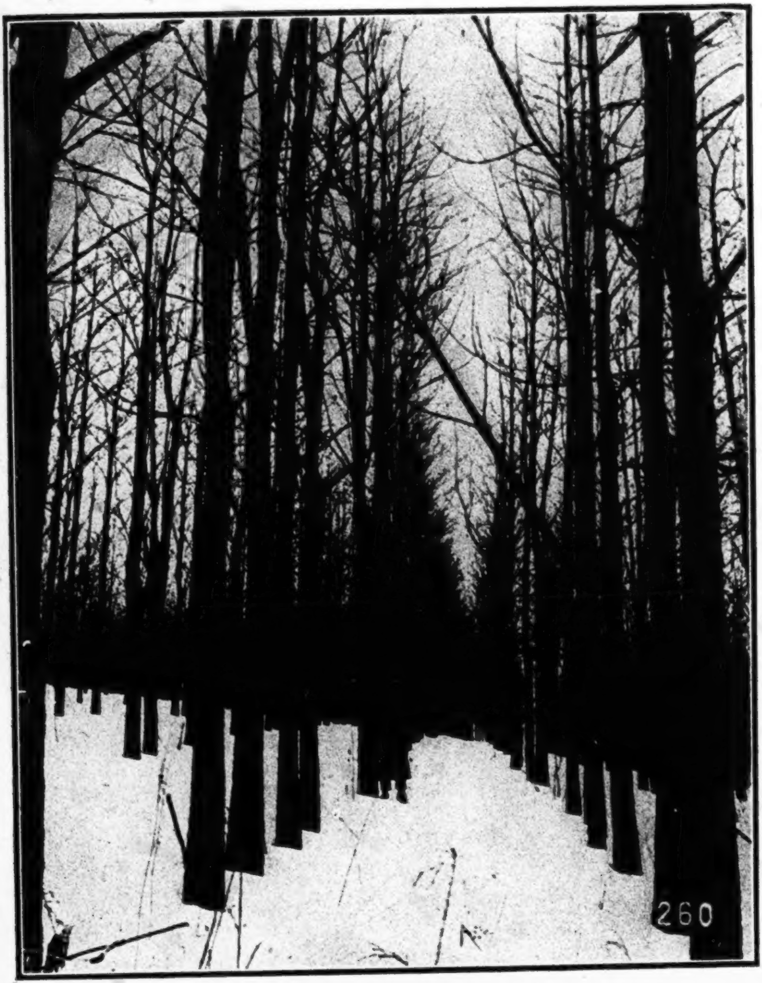
The actual area of planted timber, secured from reports covering 71 per cent of the total area of the State, is 86,638 acres. The total area of past planting is estimated at 122,025 acres, of which 110,462 acres are east of the ninety-ninth meridian. The total area of land upon which planting is desirable is 1,788,238 acres. This includes 3,000 acres of land on irrigation projects and 150,000 acres of land requiring planting in the Black Hills National Forest. Planting is reported to be on the increase in this State. Boxelder, ash, cottonwood, elm, and soft maple are the species chiefly planted, for purposes of shelter, fuel, and posts.

NEBRASKA.

An actual area of 167,137 acres of planted timber was secured from reports covering 87 per cent of the State. The estimated total area of past planting is 191,996 acres, of which 133,541 acres lie east and 58,455 acres lie west of the ninety-ninth meridian. The area in the State which should be planted is 2,093,803 acres. The total includes 900 acres of land on irrigation projects and 556,072 acres within the Nebraska National Forest. The practice of private planting is reported to be slightly declining. The species chiefly used in the past have been cottonwood, boxelder, ash, elm, and maple, for purposes of shelter, fuel, and posts.

KANSAS.

Reports were received covering practically the entire State. The total area of planted timber is 175,023 acres, of which 154,131 acres



21-YEAR-OLD PLANTATION OF HARDY CATALPA, IOWA.

PROTECTIVE AND COMMERCIAL PLANTING YANKTON COUNTY, S. DAK.

lie east and 20,892 acres west of the ninety-ninth meridian. The area which should be planted is 1,963,853 acres. The total includes 240 acres of land on irrigation projects and 302,387 acres within the Kansas National Forest. The practice of private planting seems to be about at a standstill. The species chiefly planted have been cottonwood, black locust, hardy catalpa, black walnut, and ash, for purposes of shelter and production of posts and fuel.

OKLAHOMA.

Only that portion of the State which lies west of the ninety-ninth meridian has been included in the central treeless region. The area of planted timber in this portion of the State is 21,143 acres, secured from reports covering practically the entire area of the region. The area which should be planted is 317,044 acres, which includes 5,000 acres of land requiring planting within the Wichita National Forest. The practice of planting in this region is increasing rapidly. Locust, catalpa, maple, and cottonwood are the species chiefly planted, for purposes of post production, shelter, and fuel.

TEXAS.

Only that portion of the State which lies west of the ninety-ninth meridian is included in this region. Of past planting 6,848 acres were reported from 52 per cent of the total area. The estimated area of past planting for this portion of the State is 13,169 acres. The area which should be planted is 2,507,651 acres. This includes 1,800 acres of land on irrigation projects. The practice of planting is reported to be increasing very rapidly. Black locust, cottonwood, and catalpa are the species chiefly planted for purposes of shelter and the production of posts and fuel.

WESTERN REGION.

This region includes the Rocky Mountain and the Pacific coast States. Nearly all of the forest land in the western States, with the exception of Washington, Oregon, and California, is within national forests, thus making forest planting on these lands chiefly a federal problem. Aside from this, the principal opportunities for planting occur in the valleys of southern California and on irrigated lands throughout the region. The total area of land which it is essential should be forested is over 7,000,000 acres.

PRIVATE FOREST PLANTING.

On irrigated lands the primary purpose of planting by private owners is identical with that of the central treeless region. Most of the projects are so located as to be subject to strong winds, and protection is essential. Forest planting by individuals in California includes both protection of orchards and the production of commercial timber.

The total area of planted timber in this region is estimated to be 38,862 acres, of which 37,100 acres have been done by private landowners. This estimate is based on the area of past planting actually secured from county reports. The most interesting and economically valuable planting in the region is (1) an aggregate of 20,000 acres of commercial plantations of eucalypts in California and (2) the annual planting work of a paper company in Oregon for the production of pulp wood, a total of 1,100 acres up to 1908. The former presents one of the most remarkable cases of profitable returns from a quick-growing species, and shows the value of further experiments with exotic species in the United States. The latter is a notable example of the feasibility of planting for a special purpose, even in a well-timbered region.

If the proper species of trees are used, the difficulty of securing good shelter belts and woodlots will be no greater on western irrigated lands than in the central treeless region. Eastern species of trees have proved most useful in the small amount of planting done thus far. Ash, cottonwood, locust, and elm, introduced species such as Norway spruce and Scotch pine, and many other trees have been planted. The choice of species depends chiefly upon latitude and altitude since moisture can be controlled by irrigation. There is often such a wide difference in conditions within a section of a State that different trees must be chosen. For example, in the upper Snake River Valley, in eastern Idaho, only hardy conifers and broad-leaf trees are suitable, while in the western part of the State, in the lower Snake River Valley, nearly all eastern hard woods may be grown.

There are now about 11,000,000 acres of land under private irrigation, and there will be 1,910,000 acres under government irrigation by 1911. There yet remains 60,000,000 acres judged to be susceptible eventually of irrigation. At least 3 per cent of such land may be devoted to tree growing to good advantage, and if this is done planting will have shelter as its chief purpose, but incidentally the production of useful farm materials.

The development of planting in California has been more rapid than in any other State in the region. High returns from plantations have already been secured, and the southern part of the State is likely to be a great producer of eucalyptus (hard wood) timber for many uses, especially furniture and wagon stock.

It is estimated that there are at least 1,000,000 acres of land in the valleys of southern California upon which continued irrigation for the production of fruit is not feasible, but which can be irrigated temporarily and are well suited for the growing of eucalypts. The principal work of the State in this connection thus far has been in the nature of advice and giving out publications dealing with planting.

The Forest Service has during the past few years made examinations of 15 of the 28 government irrigation projects to determine the species best adapted for planting by settlers, and experiments in tree planting are being conducted on several of the projects. Since 1900, 48 planting plans have been prepared for private landowners in the States included in the western region, covering a total of 15,779 acres. (See fig. 2.) Approximately 809 letters asking advice on planting were received and answered during the year ending June 30, 1908, of which 460 were from California; in addition, a very large amount of correspondence has been answered by the state forester. Partial returns show that 470 acres have been planted up to

GOVERNMENT EXPERIMENTAL PLANTATION OF JACK PINE, HOLT COUNTY, NEBR.

EUCALYPTUS WINDBREAK PROTECTING LEMON ORCHARD, SAN BERNARDINO COUNTY, CAL.

July 1, 1908, as the result of advice given by the Service through planting plans and correspondence.

The principal forest lands outside of national forests lie in Washington and Oregon west of the Cascades, and in California. Possibly 25 to 30 per cent of cut-over lands in the former section will be devoted eventually to agriculture. Adequate fire protection and proper forest management will provide for a future timber supply on the balance of these lands. Planting will be a small factor only and supplemental to forest management, in order to restock areas that can not reseed naturally because of lack of seed trees.

It is estimated that in addition to the national forest land requiring planting an area of 276,640 acres of cut-over private lands must be artificially reforested, and that tree planting is desirable on 2,586,340 acres on irrigation projects and other treeless farming regions. In preparing these estimates for that portion of the region not included within national forests, the area of cut-over land not restocking naturally in private ownership was found by computing from figures secured from county reports. To these amounts were added 3 per cent of the area of irrigation projects to be completed by the Reclamation Service by 1911, and 3 per cent of the area of farm land in each State, less the area of past planting in that State.

NATIONAL FOREST PLANTING.

Over 5,000,000 acres in national forests will require planting eventually. The following table shows the area to be planted by States:

State.	Area requiring planting in national forests.	State.	Area requiring planting in national forests.
	Acres.		*Acres.*
Arizona	255,000	Oklahoma	5,000
California	1,113,500	Oregon	150,000
Colorado	932,500	South Dakota	150,000
Idaho	228,000	Utah	174,000
Kansas	302,387	Washington	103,500
Minnesota	10,000	Wyoming	637,000
Montana	434,000		
Nebraska	556,072	Total	5,276,959
New Mexico	226,000		

The total area to be forested represents approximately 3 per cent of the total area of all national forests. These figures are based on the reports of supervisors and other officers of the Forest Service; in many cases the acreage has been determined by a careful examination of the forest. The areas given for Kansas and Nebraska consist of treeless sand-hill land; that given for California includes chaparral land, some of which was never natural forest land. With these exceptions the 5,000,000 acres represent natural forest land that has been denuded by lumbering and fires and which must be planted if it is ever to become productive. After considerable experimenting it may also be found possible to afforest a larger area in addition to this, such as brush lands in the arid region.

There are two principal purposes in future national forest planting—protection of important watersheds and the production of commercial timber. The distinction made in classifying protection areas is the importance of the denuded slopes in protecting the water supply of near-by towns and cities, and streams furnishing water for irrigation projects in the immediate region. Lands to be planted that have a more remote protective influence, and the chief importance of which lies in planting them to make the land productive again for future needs, have been classified under commercial planting areas. Both purposes are often involved, but the areas given above may be divided according to purpose, as follows:

	Acres.
Protective planting:	
City watersheds	280,000
Irrigation watersheds	1,485,500
Planting to produce commercial timber	3,511,459

To meet this need it has been necessary to experiment carefully in order to determine the best methods and species to use. Attention has been paid, first, to city watersheds, and eight nurseries have been established within a period of five years, having a capacity of approximately 5,000,000 trees. Not all of these have trees old enough to plant, but there are now 2,250,000 trees ready for planting, and this figure will increase annually. Two of these nurseries provide trees for planting in the sand hills of Nebraska and Kansas. This planting is to serve as an object lesson to the people and to provide useful material in the future for this region. The others provide trees for watershed planting to improve the condition of water supply in Colorado, Idaho, Utah, California, and New Mexico.

In addition to planting trees, experiments were begun recently to determine the practicability of seed sowing on the sites where a new forest is desired. Less than a ton of seed was used in 1907 in a series of experiments on 27 forests in 8 States. In 1908 over 6 tons of seed were secured to extend this work materially. Success has been obtained by this method in reforesting burned areas of yellow pine in the Black Hills National Forest. It seems likely that reforestation by seeding will be largely successful in northern forests and at high altitudes where moisture is more abundant. Planting will be absolutely necessary on the drier situations having less brush and grass cover, and especially in the southern forests.

All sowing and planting work is planned ahead for a five-year period and preceded by a careful study of the forest.

Only 1,762 acres have been forested since the work began, but this area represents many situations and conditions, and valuable data have been secured bearing on future work. In addition to this great task of reforesting 5,000,000 acres of denuded land, planting and sowing will be necessary to supplement natural reproduction in the forest, and will become a regular part of forest management in national forest work.

CONCLUSION.

Just as the greater portion of the forest area of the United States lies in the East, so the amount of land requiring restocking with forest is greater in that region. Conservative lumbering and forest planting within national forests and by private owners in the West

30-YEAR-OLD GROVE OF MANNA GUM (EUCALYPTUS) IN SUTTER COUNTY, CAL.

3-YEAR-OLD BLACK LOCUST PLANTATION ON IRRIGATED LAND, IDAHO.

will maintain a permanent supply of our valuable western conifers, but in the East the perpetuation of the best species of hard woods and conifers is dependent largely upon the activity of the private landowner. It is essential that the people of each State should realize the immense importance of individual effort in providing for a future timber supply and not depend wholly upon the results of federal or state action. The amount of land that can be restored to value through planting by the Federal Government or the States is small compared to the great area that must be forested eventually by private landowners or corporations.

WATER CIRCULATION AND ITS CONTROL.

By Bailey Willis, E. M. C. E.,
United States Geological Survey.

CIRCULATION OF WATERS.

The moisture which falls upon North America in the form of rain and snow comes chiefly from the Pacific Ocean. A smaller proportion rising from the Gulf of Mexico and the West Indian seas falls upon the eastern United States. A part of this precipitation returns to the air; another part flows to the streams; a third enters the ground. It all sooner or later returns to the oceans. In this great general circulation there are many short cuts and many stop-overs. Rain which falls upon the sea has taken a short cut. Snow which gathers in banks and glaciers, water which lingers in lakes, swamps, and especially in the soil and deeper recesses of rocks underground, has stopped over for a longer or shorter time. On the whole, the great body of moisture moves constantly, circulates in various forms through the air, on the earth, and through all parts of the superficial crust of the earth, and in its constant flow is the most vital element affecting the life of plants and animals. The very air itself is not more necessary than the presence of an adequate and fairly regular supply of moisture.

These vast movements of moisture transcend our control, but their effects do not. Has not man through intelligent skill converted the desert into a garden? And has he not through obstinate ignorance turned the garden into a desert? The path of our race from Asia across Europe has led through many such gardens; it is marked also by such deserts.

Says Irving in the charming introduction to The Alhambra:

> Though there are exceptions in some of the maritime provinces, yet for the greater part Spain is a stern, melancholy country, with rugged mountains and long sweeping plains destitute of trees and indescribably silent and lonesome, partaking of the savage and solitary character of Africa. What adds to this silence and loneliness is the absence of singing birds, a natural consequence of the want of groves and hedges. The vulture and the eagle are seen wheeling about the mountain cliffs and soaring over the plains, and groups of shy bustards stalk about the heaths; but the myriads of smaller birds which animate the whole face of other countries are met with in but few provinces in Spain, and in those chiefly among the orchards and gardens which surround the habitations of man.

No better description could be written, not only of Spain but of Asia Minor, where the marbles of Grecian civilization mark the sites of lost cities; or of Dalmatia, where barren plateaus have replaced the forests from which Rome built her navies; or of many other parts of southern Europe and northern Africa, where man has helped to rob nature of her charm and transformed her gentleness into stern severity.

We Americans have left these desert mountains behind in Eurasia; but we occupy the last land that lies toward the setting sun. Our children and our children's children for countless generations are to enjoy the gardens or bewail the deserts we create.

In the general circulation there is just one point where agencies under human control can directly affect the course of the movement. It is where rain strikes the ground or the vegetation covering the ground. From this point three routes are open to the moisture. It may evaporate, it may run off, or it may sink in. That which evaporates is lost to man's immediate use; that which runs off may be useful, but is frequently so violent as to be harmful; that which sinks in flows slowly to the springs and streams and becomes available when most needed.

Now man can send more water back at once to the air and down to the streams, or he can lead a larger proportion into the soil to enrich his crops, to feed springs, and to bear his boats during low river stages, or he can strip the ribbed rocks of soil, as witness Spain, France, Italy, Greece, and China, or he can clothe the surface with forest or verdure or thirsty fallow.

It is the object of this paper to consider the methods and efficiency of man's control, through engineering, agriculture, and forests. But before entering upon that subject we may take a general view of moisture in circulation along the several parts of the route that are commonly known as precipitation, ground water, evaporation, and surface flow.

PRECIPITATION.

Air and moistre may be mixed, as in clouds and mists, and some amount of moisture is dissolved in the air, no matter how dry it may seem. These two states of moisture in the air, whether mixed or dissolved, depend chiefly on the temperature. Changes of temperature are related to changes of barometer, and pressure has an effect on the condition. For any particular temperature and pressure the air will hold a certain amount of dissolved moisture and no more.[a]

Any effect which changes the temperature of the air makes it either more or less thirsty. A familiar instance is the cloud banner which seems nailed to a mountain top, especially to a snow peak, in spite of a strong wind. In that case a warm air current containing dissolved moisture is cooled by rising along the slope or by contact with the snow, and a part of the moisture becoming condensed is seen as a cloud. Blown further, the water particles are redissolved in warm air currents and the cloud ends; but as the conditions and changes are continuous the banner is not blown away.

A similar phenomenon may be observed over such regions as our great plains, where the column of rising air, becoming dilated and cooled, forms a rain cloud at great height, yet the falling rain is dissolved in the hot air below before it can reach the ground. No one who has seen the shower vanish into thin air will question the effectiveness of radiation from treeless plains under a summer sun to prevent precipitation.

---

[a] Dissolved here means invisibly dispersed in the air. The physical or chemical nature of solution is not in point.

Who does not know a drying wind? Such an one as blows cold from the Canadian snows and warming up drinks up moisture from every pore of the surface? Or if you have crossed the Cascade Mountains of Oregon or Washington you know how the wet air of the western ranges contrasts with the furnace dryness of the eastern plains. The mountains are wet because they are high, and they are heavily forested because they are wet. But there is also a reciprocal action of the forests on the wetness, for the radiation from the dark green expanse is comparatively uniform and promotes frequent and steady rains. Were the mountains bare they would, like the bared sierras of Spain, receive occasional but violent downpours and send down excessive and disastrous floods, even more disastrous than now.

On the other hand, the plains are dry because they are low and situated beyond the heights in the path of moisture-bearing currents, and they are without forests because they are dry. But here also there might be, yes, may be, a reciprocal action of vegetation on the dryness. For in so far as we clothe the surface with green crops we lower the temperature of the rising air and favor precipitation on the verdure covered plain.

Thus moisture, in pursuing the great globe-encircling routes of the winds, may be influenced by local conditions to stop or to hasten on. There is a cycle of reactions which begins with rain, is continued by ground water and vegetation, and leads back to rain. The showers sink in, the seed germinates, the plant grows in the moist soil, and the cool, moist air above the green surface provokes a shower; or the downpour dashes off, the bare surface radiates the heat of the brilliant sun, and the shower that might fall passes over.

These reactions are not the great ones, but they are effective enough in many regions to make a garden or a desert, as the experience of our race, viewed in the light of modern knowledge, proves.

GROUND WATER.

If anywhere in humid regions a well be sunk deep enough water will commonly be found. The water fills the soil or the spaces in the rocks. It flows into any opening and is governed by gravity, so that it runs down grade under ground. It is "ground water" and its surface is the "ground-water table."

In humid regions the ground-water table corresponds with the surface level of swamps and streams in their immediate vicinity, but it rises above them in uplands, following in a measure the altitude of the surface, though it does not reach an equal height. From the higher parts the ground water flows down to the lower; that is, from the uplands underground to the streams. If it be replenished by frequent rains it feeds the streams steadily. If not, the supply diminishes at first rapidly and then very slowly. It is the principal source of moderate and low-water flow in rivers of the eastern United States.

In arid regions the ground-water table usually lies at considerable depth or is wanting. Underground water may even be restricted to deep water-bearing strata, which it enters along the outcrop and in which it is under artesian head.

In all regions, except excessively dry deserts, the soil above the ground-water table contains some moisture, which envelopes the grains with a thin film only, if the soil be very dry, but which otherwise occupies the minute spaces between the grains. This moisture does not fall or rise in obedience to gravitation, it being under control of forces due to surface tension, which exist in tubes of very small bore (capillary tubes) and similar minute spaces. These forces of surface tension, overpowering the effect of gravitation, draw the moisture upward or sideways or downward in the direction of least moisture and thus tend to establish a balance throughout the mass so far as the capillary films are continuous. If there be evaporation from the surface the moisture is drawn upward, and this is the principal effect due to capillary attraction.

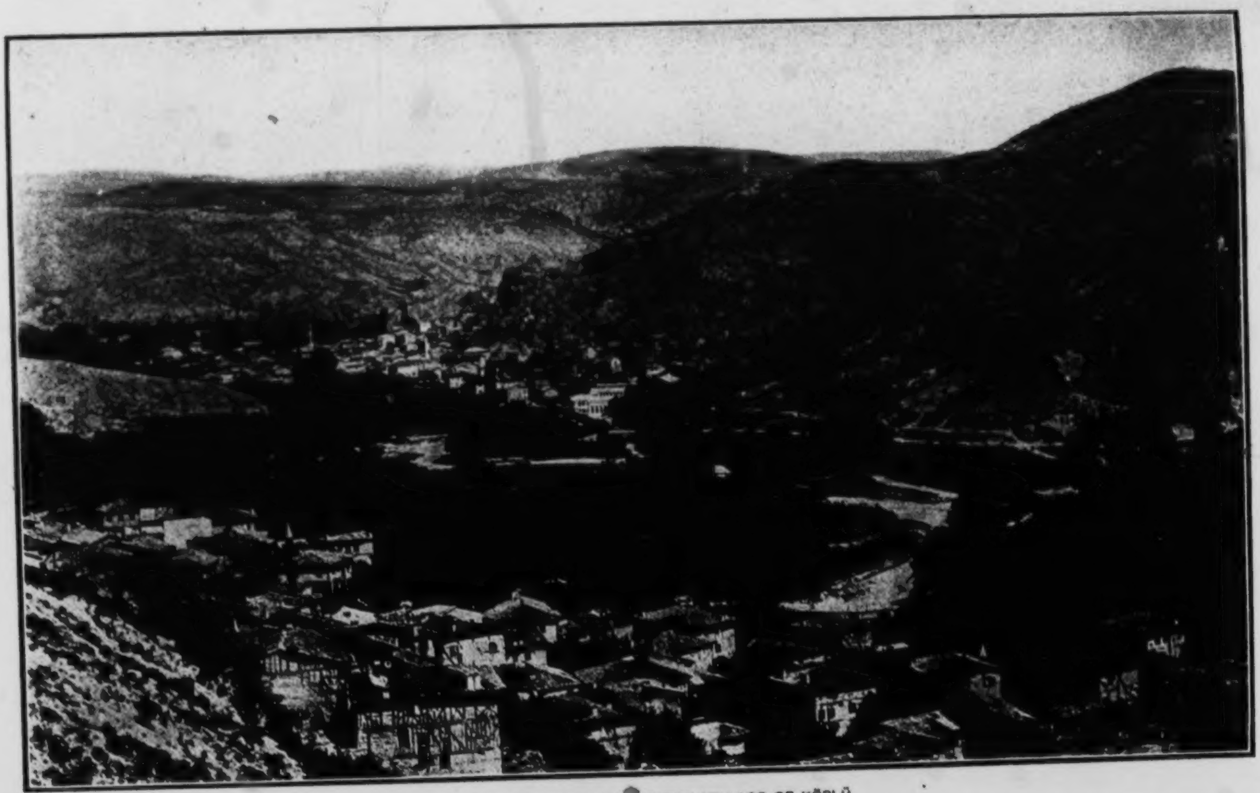
In humid regions the ground water and the soil moisture are in contact. From the surface of the ground to the water table the soil is more or less moist, and if evaporation takes place the upward movement may extend down to the water table, and some part of the ground water may be drawn into the capillary circulation.

In arid regions the ground water and soil moisture are commonly not connected, but are separated by a greater or less space in which the capillary films that envelope the soil grains are not in contact and there is consequently no capillary circulation. This is true under much of the great plains. Streams are there fed only by immediate flood run-off or by underground waters from remote mountains.

Both ground water and soil moisture are derived from precipitation; the soil moisture in any area being part of the rain or snow that falls on that area; and ground water also being often accumlated from the surface which it underlies, but frequently coming from higher grounds near by or sometimes far away. This fact places in the farmers' hands the power to regulate the most vital thing in making a crop, by seeing to it that rain goes into the soil and not over it or away with it.

EVAPORATION.

When dry air passes over a moist surface it absorbs moisture from the latter. This is the simple process of evaporation, which is, however, subject to intricate relations of temperature, pressure, and humidity. Considering it as a way in which water that we want in the ground escapes into the air, we are interested to limit evaporation. This is possible by keeping the surface cool and the air above it moist, as under trees; and in sufficiently arid regions it is accomplished by covering the surface with a dry mulch, which cuts off the upward rise of moisture. The action of the woods in keeping the air and ground cool and moist is not open to question; even on the semiarid plains a wind break notably reduces evaporation from the fields in its lee; but it is held by some writers that the trees draw in through their roots and transpire through their leaves more moisture than would evaporate were the soil beneath them bare. This is true with regard to the soil reached by their roots, particularly on plains. On hill slopes it is also true, but trees so increase the amount of water stored in sloping ground, over that which can be stored in the same slope if bare, that they more than make up for what they transpire.



NO. 1.—ASIA MINOR. VIEW OF THE VILLAGE OF KÖPLÜ.

In regard to the manner of evaporation from soils under arid and humid conditions we may best quote as follows from Buckingham:[a]

> When a moist soil dries by contact with the air above it the loss of water takes place by evaporation close to the surface, the amount lost by direct evaporation from points several inches below the surface being in general negligible. As the surface soil dries out a moisture gradient is established, and the dry surface soil draws up water from the moister region below by capillary action. If this capillary flow of water be prevented or lessened, as by the use of a mulch, the escape of water is decreased, because the evaporation has, on the whole, to take place from farther below the surface, so that it encounters greater resistance and is slower.
>
> The flow of water in a soil which is not very wet has to take place through the thin films in which a part of the water is distributed over the soil grains. If the soil becomes very dry it is to be expected that these films will become thinner or break, the resistance to capillary flow increasing very much in either case. Hence it is to be expected that in very dry soils capillary flow will be slow.
>
> Suppose a soil could be made so dry that no capillary flow at all would take place in it even when it was in contact with a moist soil. Such a layer of soil would act toward the moist soil below it as a protecting mulch. A soil can probably not be made so dry as to lose its power of capillary conduction of water entirely, but we may get an approximation to this limiting case.
>
> Suppose that after a rain the soil surface be exposed to very arid conditions with a high surface temperature and a hot, dry wind. The surface of the soil will lose water much faster than it can be brought up from below by capillary action, and if the arid conditions be kept up a layer of dry soil will be formed on the surface, which may be so dry as to act in the manner suggested, i. e., as a protecting mulch. We shall thus have an initial period of very rapid evaporation, followed by a period of slow evaporation, taking place largely from below the surface.
>
> If the same soil had been subject to less arid conditions the initial loss would have been less. The capillary flow from below would have been sufficient to prevent the surface soil from becoming dry enough to act as a mulch; hence, though the initial rate of loss would be smaller, that rate would not fall off so rapidly. It might even happen that in the long run the soil under the arid conditions would actually lose less water than the same soil under humid conditions.

From these statements and the careful experiments on which they are based it appears that in humid regions evaporation from a bare surface is not readily controlled, whereas in arid regions the precious moisture may be retained by a mulch of sufficiently dry soil.

SURFACE FLOW.

Surface flow is the water in swamps, lakes, and streams. It is all derived from precipitation, but is gathered from the surface in part only; another part appearing from seepages and springs after a trip underground. The former we will call "flood run-off," the latter "seepage run-off."

Flood run-off is that part of rain or snow fall which remains on or very near the surface, flows directly to swamps, lakes, or streams, and immediately or in a short time runs away. Following showers, flood run-off raises streams; following prolonged rains or melting snow it occasions high water, which quickly recedes when the rain or melting ceases; and following excessive rains or melting, flood run-off produces great floods.

Flood run-off is thus the most transient, irregular, wasteful, and dangerous part of precipitation.

---

[a] Buckingham, Edgar: Studies in the movement of Soil Moisture. U. S. Dept. of Agriculture, Bureau of Soils, Bull. No. 38, pp. 18–19, 1907.

It damaged the people in the United States in eight months, January 1 to August 31, 1908, to the extent of $237,000,000. In the year 1907 it occasioned the loss of $118,238,000. In the ten years prior to December, 1906, it cost not less than $1,500,000,000 in goods, buildings, bridges, roads, railroads, and real estate, washed away.

These losses are net losses; they do not include deterioration of values not actually destroyed, nor do they cover the incalculable, irreparable loss of fertile soil from our mountains, grazing lands, and fields. This loss amounts to approximately 1,000,000,000 tons of soil per annum. Nor does the financial loss include the sum of human suffering or the loss to the nation through lowered efficiency and morale of the citizens who suffer from floods.

Seepage run-off stands in direct contrast to flood run-off. It is slow and gradual where the other is quick and spasmodic; it is regular where the other is irregular; it continues when the other fails. The uses of surface waters (crop growing, city water supply, sanitation, water power, and navigation) depend on reliability and regularity. Hence it is obvious that the works of man should be designed to increase that part of rainfall and snowfall which, sinking into the ground, contributes to seepage run-off, and to regulate the flow of that considerable part which can not enter the ground.

Rain falling on a well-tilled field or grass or forest largely sinks in. Falling on bare, baked, incrusted ground, it dashes off. Whichever in any place occurs, some farmer or herdsman or lumberman is responsible, for there is now no considerable part of the United States that man does not make or mar. But at the best there will always remain a notable proportion of precipitation that will form flood run-off, and this we must commit to the care of the engineer as part of the surface flow which it is his duty to control.

OUTLINE OF METHODS OF CONTROL.

ENGINEERING CONTROL OF SURFACE FLOW.

The engineer aims to regulate surface flow through methods of storage, diversion, or confinement in an established channel. His selection of method is determined by the topographic conditions of the particular locality primarily, and also by the balancing conditions of need and cost. The result is a reservoir, canal, or other structure designed to be permanent, to meet the greatest emergency which may arise, and to supply such water or afford such relief from water as conditions require. When practicable the investment should return to the people at least a fair interest on the cost. These limiting conditions are so well understood and engineering practice is based upon such a thorough knowledge of fundamental mechanical principles that in any given case the engineer's calculation may be implicitly trusted, provided that the factors of run-off, fluctuation, and sediment, which are fundamental elements of the problem, do not at any future time exceed the maximum limits which past experience leads him to assume. This provision implies that the progress of settlement and the exploitation of our natural resources should not unfavorably modify the relation of run-off to ground storage and evaporation. Through ignorance, carelessness, and greed, the farmer, herdsman, and lumberman are constantly violating this provision, as we

shall see when we come to the consideration of the specific relation of their activities to the partition and distribution of precipitation. The engineer is now called upon to regulate run-off, the irregularity of which is persistently aggravated by these widespread activities; he is required to take care of sediment whose volume is constantly increased by vicious methods of agriculture, grazing, and deforestation, and the nation collectively spends millions on engineering while the people individually render the expenditure useless.

The engineer urgently needs the support of an educated, enlightened public opinion which will control individuals. In proportion as every landowner manages his property intelligently with regard to its perpetual value and the welfare of the commonwealth, the engineer's problem will shrink within those limits of reasonable magnitude and cost which it now threatens to exceed.

Let us consider some examples of the engineer's methods of regulating surface flow by storage, drainage, diversion, and canalization.

The construction of reservoirs for the storage of waters is in comparison with its possibilities very slightly developed in the United States. A few examples will illustrate the magnitude and purposes of existing works.

The Croton reservoir system cost Greater New York $86,359,562 up to 1898, and estimates on extensions and improvements are $161,000,000. The city can afford it, for the system supplies pure water to 4,000,000 persons, among whom, considering one benefit only, the death rate from typhoid fever was, in 1905, 16 per 100,000, as against more than 100 per 100,000 in certain cities supplied with polluted river water.

On the upper Mississippi a reservoir system has been gradually installed since 1880 to control high and low stages of the river for navigation. Lake levels were raised and low, flat lands were flooded. The topographic conditions were favorable and the cost for lands and improvements submerged was low. In sixteen years the Federal Government expended $1,525,000.[a]

Storage reservoirs for irrigation waters were established in the arid West by private enterprise in the early settlement of the regions, but work on a large scale began after the passage of the reclamation act, in 1902. The Reclamation Service has 28 projects in various stages of progress. They will make available for homes 1,910,000 acres, at a cost of $70,000,000, or $36.65 per acre.[b]

In any particular case the cost per acre-foot of storage capacity depends chiefly on the topographic situation, which determines the magnitude and character of the structures, and on the value of property to be displaced or submerged. In general, it costs less per acre-foot to store a large body of water than a smaller one.

The efficiency of a reservoir may be said to be its capacity to retain the water which ought to be stored. If it will hold all the surface flow of its drainage basin, less the amount used and evaporated during any time, its efficiency is 100 per cent. In proportion as it fails to do this during floods its efficiency falls below the maximum. A reservoir which will have an efficiency of 100 per cent is being built by the Reclamation Service on the Rio Grande above El Paso. It will retain more than the entire annual precipitation, approximately three times the surface flow of the drainage basin, and when it is completed floods which have been disastrous will be absolutely abolished.

---

[a] Annual Report, Chief of Engineers, U. S. Army, part 2, p. 1439, 1906.

[b] Blanchard, C. J.: Home-Making by the Government. Nat. Geogr. Mag., April, 1908.

If other conditions are alike, the efficiency depends on the amount and distribution of the waters from rain and snow melting. These vary according to broad districts. The factor which primarily determines cost, namely, the character of topographic basins which may be dammed, also varies broadly, and according to the distribution of these two factors we may distinguish at least four regions which are unlike in regard to storage possibilities.

The arid plains and basins of the West afford conditions of minimum or moderate cost and maximum efficiency for reservoir storage. The experience of the Reclamation Service has been cited.

Another region where reservoirs of moderate cost and adequate efficiency are possible is that of lakes and swamps which lie within the area covered in a recent geologic epoch by the great ice sheet. It includes parts of the Dakotas, Minnesota, Wisconsin, Illinois, Indiana, Michigan, and, in a less degree, New York and New England. In this region there are thousands of lakes, each one of which is a natural reservoir, and many more swamps, each one of which is a shallow, but practicable, reservoir site. The experience with the government dams on the upper Mississippi gives the best insight into the value of these reservoir conditions.

A third district which may be distinguished with reference to the possibilities of reservoir storage is found in the prairie States—Iowa, Illinois, and Ohio—and in areas of similar topography, population, and precipitation. In that part of those States which lies outside of the old ice limit, streams as a rule run in ravines or narrow valleys, which, however, have moderate fall and would, in many localities, afford practicable conditions for reservoir storage. The cost of farm lands and town sites which must be submerged is such, however, as to render capacious reservoirs too costly, provided any other means of control be practicable. Here the question of cost will limit the construction of large reservoirs. The lands are farmed and upon the farmer must rest the responsibility to the nation for a proper regulation of the water flow. The topographic character of the region is favorable to the construction of large numbers of small reservoirs to catch the flood run-off from nearby fields, and this item in farm equipment should become as much a matter of public interest and control as the maintenance of public roads. But the silt from badly tilled fields will render reservoirs useless unless the farmer prevents erosion. The larger factor in control must be found in improved methods of tillage and crop rotation.

A fourth district which presents special conditions in regard to storage is that of the Appalachian Mountain region. Here topographic forms are such as to render reservoir construction both difficult and expensive. The narrow valleys alone offer possible sites. Their steep gradients necessitate high dams for reservoirs of moderate capacity. Where wide bottom lands afford better opportunities, important towns are commonly located. Moreover the efficiency of such reservoirs must be low, because the flood run-off is torrential and some considerable part of it must be permitted to escape. We may not, however, conclude that reservoirs are impracticable.

NO. 5.—VIEW AT THE IRON GATE ON THE DANUBE IN SOUTHEASTERN AUSTRIA.

Overlooking a portion of the Transylvanian Alps, which are maintained under forest cover except on gentle slopes. There is striking resemblance in topographic forms and physical conditions to those of the Appalachian Mountains south of Pennsylvania. (Photo by B. W.)

A region in which forests have been properly cared for and exploited, and in which the slopes are carefully protected by covering of forest or grass with proper attention to methods of culture that prevent erosion. The field on the left is being cultivated. It may be noted that the furrows are all strictly horizontal. (Photo by B. W.)

The Appalachian Mountains have always had and will always have special relations to national development. Their mountain wall guarded the colonies during a century of French and Indian warfare. Eventually occupied by American enterprise, the region became through its resources in minerals, lumber, and water power a dominant source of national strength and wealth. It can never support a large agricultural population, yet the mountain dwellers will cultivate their fields in its upland valleys so long as the soil remains. Its mineral wealth will certainly be exhausted, but its forests and streams, those two intimately related and most valuable factors in the nation's prosperity, need never be impaired though continually used.

These mountains possess a power to do harm which is not less than their power to confer benefit. The floods that gather from their rills traverse the richest cities, manufacturing districts, and valleys, and exact annually an enormous tribute. The cost in dead loss, in lessened values, and crippled industries will eventually force the nation to protect itself. There are men—engineers, too—who believe they can fetter the full-grown flood, but the Commonwealth which trusts to them alone and neglects the agencies of forestry and agriculture that divert the raindrops will suffer till it has bought wisdom dearly.

Thus throughout this mountain region the problem of controlling surface waters is not only particularly difficult, but its solution is peculiarly important. The engineer has here a grave and difficult task to perform, and even under the unfavorable local conditions the storage reservoir must take its place as one of the features of the system of regulation.

In our general discussion drainage is next. It stands in direct contrast to storage. It promotes quick discharge, increases flood run-off, and dries up swamps that storage would convert into reservoirs. No region from which injurious floods gather should be drained, for the drainage system will increase the floods. On the upper Mississippi, for instance, we would not drain the reservoirs produced by artificial dams, nor should we drain swamps that empty into them or into the river below them without duly considering to what extent our left hand is undoing the work that our right hand has done.

Yet drainage has its place in the national management of surface waters. It is appropriate in lands liable to overflow and which may safely be permitted to return the waters promptly to the stream as the river falls. It is permissible in lands whose value when drained exceeds the value of lands that the drainage waters may submerge. Here, as indeed generally, throughout this whole question of conservation the resulting value determines whether or no the thing should be done.

Diversion canals are designed to take a part or all the water of any system and conduct it from the channel in which it may be wasted or become harmful to the point where it shall be applied to some useful purpose. A mill race is a diversion canal on a small scale, and the Chesapeake and Ohio Canal, which diverts a part of the waters of the Potomac to a channel where they may be useful to navigation, falls in a similar class. In connection with the irrigation projects of the Reclamation Service, diversion canals constitute an important feature. In some instances they lead directly from rivers which are capable of furnishing sufficient water at all stages; in other instances, they lead from reservoirs where water is stored to maintain the desired flow when the tributary streams would be inadequate to the purpose. In none of these cases has the diversion canal any special relation to the conservation of water. It introduces a siding in the general through route of circulation and discharges its water freight at the point where it is wanted. It serves in some measure to regulate surface flow, but that object is subsidiary to a major purpose, which may be power or irrigation or navigation.

Canalization is a method of river control which consists in reducing the river to the condition of a canal by the introduction of dams, locks, and sluice gates. The current of the open river is then replaced by slack water. The discharge is permitted through locks as required by passing boats, or over sluiceways when the volume of flood run-off becomes greater than the amount which can be safely stored in any reach of the river between dams. The most important project for canalization is that of the Ohio River, concerning which we may quote from the report of a board of army engineers, dated December 15, 1906.[a]

The board finds—

> that a 6-foot navigation at low water can be established in the Ohio River from Pittsburg to Cairo by the construction of 45 locks with movable dams, at an estimated cost of $50,962,266, in addition to funds heretofore appropriated and authorized; that a 9-foot navigation over the same length of river can be established by the construction of 54 locks and dams, at an estimated cost of $63,731,488. * * *
>
> The board gives exhaustive consideration to the question of present and probable commerce, both down stream and up, and it appears that the present commerce of the river is approximately 9,000,000 tons per annum, of which a large proportion is downstream. Having in view the fact that a canalized river offers an upstream navigation lower in cost and quicker in transit than an open-river project, the board, arguing from the known natural resources of the section and its population, concludes that a river improved by this method will afford facilities for the cheap exchange of mineral, agricultural, and manufactured commodities, which from their low value and bulk can not be exchanged unless such cheap facilities are offered, and that there is every probability that the improvement of the Ohio River by canalization, as proposed, would induce a very large future commerce, which does not now exist, in addition to retaining and greatly facilitating and cheapening the commerce which the river now bears.

In discussing the maintenance of the 9-foot project, the board estimates it at $800,000 per annum, not including the dredging of silt, which would accumulate in slack water, or at $1,000,000 per annum if this item be included.

This project, which was reviewed and recommended without qualification by the Board of Engineers for Rivers and Harbors, in a report dated October 18, 1907, has for its object the single purpose of promoting inland navigation, and it illustrates clearly the relation which any plan for canalization of a stream bears to the general problem of water circulation. The plan deals with the water after it has reached a navigable river, when it is no longer a question of control of surface waters, but merely one of more or less effectively regulating their distribution and flow. The delay which may be imposed by storage in slack-water basins is not an appreciable factor

in reducing the damage due to floods such as those which now annually work havoc in the Ohio Valley. Moreover, the project itself establishes interests which lie within the zone liable to flood, and in proportion as it is successful and such interests grow in value, so grows the necessity for diminishing and preventing floods. Thus canalization bears the same relation to plans for conserving and controlling water circulation that any concentration of civilization bears to it. It increases the burden of responsibility for proper measures of control, whether in detail as applied to raindrops or in gross as applied to flood run-off, and the larger the wealth to be protected the greater the justification for large expenditures on account of protection; but more than this, for it is not a question of engineering and financial expense alone, the larger the national interests involved the greater the individual responsibility of every patriotic citizen to his local community and to the commonwealth in general for a proper discharge of his obligation to take care of his share of the nation's assets.

CONTROL OF GROUND STORAGE AND RUN-OFF THROUGH AGRICULTURE.

On a reasonable estimate one-half of the domain of the United States must eventually be farmed to maintain the population and prosperity of the country. The essential characteristic of the great farming area, exclusive of irrigation districts, is that it shall have soil and sufficient rainfall. Rain falling on soil is partly stored as ground water, but also partly runs off. The stored water is absolutely necessary to the farmer's prosperity, which will increase as he increases ground storage; the other is wasted, and if it causes erosion is destructive.

In considering the relation of the farmer's activities and the methods which he can employ to increase ground storage and decrease erosion we must distinguish between lands that are level or nearly so and lands that have a more or less pronounced slope.

Water control on plains.—In regions of great plains or plateaus, where lands are level or nearly so, the methods which may be used by the farmer to increase ground-water storage are the methods of good tillage which at the same time yield the largest crops. They consist in deep plowing, proper cultivation during the growing season, crop rotation, and the maintenance of an open condition of the soil during periods of fallow. The object of these methods is to increase the capacity of the soil reservoirs and to open and keep open the channels through which the rain or melting snow has access to them. Run-off and erosion are restricted in proportion as this aim is secured.

To grow large crops takes a large amount of soil moisture. The soil gets it directly from rains or in seasons of drought from the ground water which is supplied by rains that pass down through the soil to the water table. The rain that soaks in is stored for the crop. The rain that runs off is taken from what might be stored, and is not only lost but, being muddy, is also lost soil. Good tillage reduces these losses by maintaining those conditions of soil and subsoil under which a large proportion of a given rainfall will be absorbed.

In general, we say that an open soil will absorb most water. The openness of texture of a soil depends upon the sizes of the particles of which it is composed and the relative numbers of particles of these several sizes—that is, its mechanical composition. There is for any kind of soil a state at which it is in the loosest and best physical condition—that is to say, a state of arrangement of soil particles according to size and spacing in which there may be the largest amount of water gathered about the particles as capillary films and between them in delicate columns. The condition is one which is well known to farmers as that which will yield the best crops. This mechanical condition of the soil is reached by plowing, harrowing, and cultivating when the soil is neither too moist nor too dry.

The facility with which rain enters a soil depends upon its being in the above-described condition—open, yet not too open. The films of water within it are then of such size and are so distributed that they support the open texture. When rain falls it enters each little capillary tube between the grains and penetrates rapidly in the many minute channels. Thus the soil, though moist, absorbs more water than if it had been drier to begin with.

When soil is very dry and powdery rain does not penetrate far into it. There are several conditions that produce this well-known result. Much water is used in filling the large volume of the small spaces between the soil grains; the capillary films are still separate at the bottom of the sinking moisture and they sink deeper only as they join, and the air in the soil, being imprisoned by the water that fills the upper layer, offers effective resistance to percolation.

The absorbent character of a soil determines the amount which the immediate surface will take in, but it does not determine the rate at which water will soak into the lower layers of the soil and subsoil; if the latter is impermeable, the pores of the surface soil may become so filled that no more water can enter, and the rest of the rain runs off. This happens when a heavy rain falls on a field that has been plowed only 3 or 4 inches deep, leaving an unbroken clayey subsoil. If the field is level, pools of water will stand over it till they dry up. If the field be on a slope, the gathering water runs off along and across the shallow furrows and takes more or less soil with it. Where the subsoil is broken to 12 or 14 inches by deep disk plowing the same heavy rain sinks in completely and is stored for the crops when needed. The soil also stays.

Thus on plains the conditions which affect percolation of rain into the soil and subsoil and which are consequently to the advantage of ground-water storage are—

(*a*) That the cultivated surface shall be level or but gently sloping;

(*b*) That the surface soil shall be in that condition which is best described by the gardener's term of "live soil;"

(*c*) That the lower soil and subsoil should afford the largest possible amount of space into which the water from the surface may run.

Another means which is at the farmer's disposal is that of crop rotation. Clean cropping year after year exhausts the plant food and humus of the soil, affects unfavorably the mechanical condition of the soil, and brings it into a state in which its fertility is greatly reduced and it is most easily eroded. In order that these effects should be prevented it is important to introduce a rotation of crops, including grass or clover, whose deep and thickly matted roots help to open up the texture of the soil and to restore that essential constituent, humus.

We have thus far considered only how the farmer can produce a condition of the soil and subsoil which will reduce run-off and increase ground storage. It is also important when the water is in the ground to keep it there, except as crops need it. It should not be wasted by useless plants nor by evaporation.

The waste by weeds is obvious. A growing weed takes water which the useful crop might have. The remedy—keeping out weeds—is equally obvious and is limited simply by cost.

Evaporation exhausts ground water most effectively when there is free circulation from the ground water to the surface. This happens when the films of water about the soil grains are in contact and there is ready movement in them. As the water immediately at the surface is vaporized, an additional supply is drawn to the surface through the capillary films from below. This is evaporated in turn and more is drawn up, and so through evaporation and capillary attraction the soil moisture is gradually dissipated into the air.

That condition of dryness which stops the upward movement of ground water by breaking the continuous water films is not readily established in humid regions, where the ground water lies not far below the surface and rains are not infrequent. Thus it appears that since in humid regions the farmer can not effectively restrict evaporation, he must resort throughout the entire year to every method of cultivation, and from year to year to the method of crop rotation, to keep his ground in the best possible condition for the largest storage of ground water, from which will follow also the largest return of any one crop. In the arid region nature comes to the aid of the farmer and gives him a means of stopping the loss of the precious moisture of which under the best conditions he can scarcely conserve enough.

When the farmers of America understand how to store and keep water in the ground they will have learned how to grow larger crops. Our average yield of wheat instead of being as it now is 14 bushels to the acre will then be nearer the average yield of Great Britain, 32 bushels.

Water control on slopes.—In regions where steep slopes are cultivated the methods appropriate to level fields find their application also, but they are insufficient, for the tendency of the water to run off lessens the time of its contact with the surface, and thus increases the proportion which escapes at the expense of the proportion that is stored. In a like degree erosion begins and is maintained on slopes, the soil is undercut and removed, and the subsoil or rock exposed. Forests would prevent this, but if the steep slope is cleared for cultivation it is necessary to substitute a series of steps for the smoothly inclined surface, in order to reduce these effects to a minimum.

This introduces a condition which is not yet necessary in America to any great extent, but which is general throughout Europe and Asia, namely, terracing. The object is to catch rain and snow on a level. The level may be the furrows of a plow or of a harrow, provided the slope be so gentle that these suffice to hold back the water and prevent it from running and gullying the fields. On steeper slopes the harrow and the plow are inadequate, and the farmer is obliged to introduce low steps or terraces which vary in character from a little bank of sward to walls of stone. The fields above the banks of sward or above the stone wall are carefully leveled and the water which falls upon them is retained. Agriculture is thus extended not only over far-spreading plains and lowlands, but up the steep banks of river gorges and ravines. The famous vineyards of the Rhine are planted on rock wall terraces, on steep slopes such as we abandon to erosion. As our population increases and the demand for agricultural land becomes more urgent we, too, will build terraces, and high river banks throughout the humid regions will grow special products. Land hunger will eventually force us to it—not soon, however—and in the meantime our steep cleared lands can not be left a prey to erosion. They must be recovered where gullied and must be protected from gullying by watchful care, such as that which guards Holland from the sea. Our enemy is no less dangerous, not a whit less insidious and persistent. Since terracing is a possibility of the future only, we must restore the forest trees. They have held the soil during ages and in them we can confidently rely.

We are wont to think that reforestation is a need of high mountains only, but the need is not thus limited. It extends to all steep cleared slopes. Thousands of miles of these stretch along our rivers, from Georgia to Maine, from Mississippi to Minnesota. Throughout the humid region they border every river. Along all their length, in all their ramifications that penetrate the richest agricultural districts, they must necessarily be covered by trees.

From the plains and gentle slopes appropriate to farming there rise in all hill and mountain districts steeper slopes that are not appropriate to farming. When farmed they are quickly eroded and destroyed. It may be set down as an obvious economic principle that no land is appropriate to a use which destroys its usefulness. This principle is not affected by the fact that ignorant persons clear and cultivate such land extensively. In the southern Appalachian Mountains it is commonly but five years from virgin forest to abandoned fields. The mountain slopes are not agricultural lands. Themselves destroyed by erosion, they damage other lands and the water courses below them. When that damage is assessable by law upon the ignorance that causes it, agriculture will be restricted to appropriate fields.

CONTROL OF RUN-OFF THROUGH GRAZING.

About 25 per cent of the area of the United States is so situated with reference to topographic and climatic conditions that it will best raise hardy grasses and must be devoted chiefly to grazing. The principal area is that of the great plains, extending from northwestern Montana around the base of the Rocky Mountains to Texas, but including also portions of the basin region on the west. Within this area the governing condition is a meager precipitation. The soils are appropriate to agriculture, the mountain ranges above the plains are suited to forestry, but both agriculture and forestry require more water than the grass that feeds herds, and they are accordingly limited in distribution in this region. The herdsman's prosperity depends absolutely upon the grass. It is proved beyond dispute that overgrazing injures the grass, partially removes the protective cover, and promotes erosion. Erosion eventually results in the removal of all herbage, produces bare, gullied badlands, and makes restocking with grass impossible.

Showing the denuded hills, the shallow, stony soil which remains after the loam has been washed away, and the sheep whose grazing removes the slight protective cover of vegetation and promotes the final process of erosion. (Photo by B. W.)

The method available to the herdsman for the limitation of run-off and the prevention of erosion is to increase the stand of the natural grass cover, upon which alone his herds depend. In some small areas he may find it necessary to adopt the usual methods of agriculture to check erosion, establish soil, and re-cover the surface with grasses, but in general that which any intelligent herdsman does to maintain the range upon which his herds live is that which he must do to prevent erosion and to limit run-off. Thus intelligent grazing promotes both individual and general welfare.

The preservation of grass upon the semiarid plains is of vital interest, probably, to the farming States, Minnesota, Iowa, and Missouri, and even more so to eastern Nebraska and Kansas. If it be true, as stated in the opening discussion of conditions of precipitation (p. 688), that radiation from the hot plains checks rainfall, it would follow, should they be eaten bare and eroded to badlands, that the semiarid climate would extend eastward. The plains themselves would become more arid, the farming districts adjoining them would be affected by prolonged droughts, and the climate would be unfavorably modified as far east as the western margin of the moist-air currents that flow north from the Gulf. Iowa is interested in the grass that grows in western Nebraska.

FOREST CONTROL OF PERCOLATION AND RUN-OFF.

The areas which must be kept forested in North America comprise 26 per cent of the whole continent. Of the United States 19 per cent requires forest protection or will grow trees more profitably than any other crop. The necessity for this amount of forests rests on two imperative economic conditions, (1) the value of forest products, and (2) the protection forests afford to other essential needs and activities of civilized communities.

It is not proposed here to discuss forest products, except to point out that their value maintains forests in areas where agriculture might be pursued if the forest products were not more valuable than the possible agricultural products. The distribution of forests, considered with reference to their products, is wholly one of cash returns. On this basis alone, however, the percentage area now left us can not economically be reduced until the increasing population begins to feel a scarcity of grain. The present price of lumber, the search for substitutes, and the coming timber famine sufficiently prove this.

Forests protect all civilized activities that depend on a regular supply of clear water or that are liable to injury from irregular and excessive flood run-off. They are not the only protecting agency. We have discussed the very great importance of engineering and good tillage in this respect. But wherever they grow forests do protect, and they do grow and protect where no other agent economically can.

This truth is challenged, for we inherit the habit of the ax and the saw, and the effects of our reckless use of these tools are not yet so conspicuous as to be clearly distinguishable in the gross result of natural and artificial activities. The challenge can not stand, however, against any fair consideration of the relations of forests and water in contrast to those of bare slopes and water.

In the opening pages of this paper we considered those phases of water circulation that are known as precipitation, ground water, evaporation, and surface flow. Forests affect each one of these, and each will be discussed in turn in the order named, so that we may clearly distinguish the several aspects of controverted points.

Forests in relation to precipitation.—Precipitation consists of rainfall, and in cold climates of snowfall, also, and these two kinds of precipitation are differently affected by forests. Concerning forests and rainfall, unqualified statements have led to exaggeration and contradiction by which the real facts are obscured. When a vast plain like the upper Mississippi Valley from St. Louis to the Great Lakes is cleared and brought under cultivation, no notable change in the amount of precipitation is likely to follow, for the air currents which sweep over it come from the Pacific and from the warm humid atmosphere of the Gulf. They are loaded with moisture and are driven north toward cooler zones. Rain falls from them inevitably, in spite of any minor effect of radiation from the fields of Illinois or Ohio. Were the wide surface stripped of green and soil and left a region of rock and sand, as central Asia was,[a] then local radiation would doubtless increase the irregularity and violence of rains, but the air rising from our fields of grain, though not as cool as that above a forest, is not so heated as to materially affect the powerful rain-bearing currents. Moreover, the general evenness of altitudes and uniformity of radiation from the green covering over a wide area tends toward regularity of conditions and gradual rather than violent changes. The ocean of green, whether of trees or grain, ameliorates the climate in like manner, though not in like degree, as does an ocean of water. Hence it is reasonable to expect that the total precipitation and the run-off, as indicated by stream gages on rivers fed from this region, will not show any decided change as a result of deforestation. This appears to be the fact, though careful observations of rainfall and run-off have been too recently begun and are made at stations too far apart to give satisfactory data for comparisons.

Deforestation of a mountain range presents a different case, since in the long run it results in extensive erosion and bare surfaces. Leaving this last statement to be discussed under Erosion, we may compare rainfall on wooded mountains with that on barren ranges on the basis of extended human experience. The mountains of southern Spain, the Pyrenees, the Basse-Alps of southeastern France, the northern Apennines, the Dalmatian and Grecian hills, have all been stripped and eroded. The change from green-covered slopes to brown bare steeps has been accompanied by a change from beneficent rains to destructive downpours. Statistics of precipitation in earlier times are not available for comparison with those of the present, but historical evidence is entirely adequate to prove that deforestation of a mountain range has modified the conditions of precipitation in such a manner that occasional heavy destructive rains replace gentle and more frequent showers, at least in the countries mentioned.

These countries differ from northern Europe in a measure as the semiarid region west of the one hundredth meridian in North

America differs from the Mississippi Valley. To this fact is due in large part the difference of opinion which exists among European writers as to the influence of forests on precipitation, springs, and run-off. Those who have observed in northern Europe the effects of deforestation of flat lands under humid climates minimize or deny entirely any influence exerted by forests; while those whose experience is with warmer, more arid, and consequently more critical conditions in mountainous southern Europe are convinced that forests exert an important beneficial influence upon rainfall, ground storage, and surface waters. To cite the latest conclusions we may quote from Cipolletti.[a]

> It is generally admitted that regions covered with forests have a lower temperature than the open country, and the reason assigned for this is the evaporation from the surface of the leaves moistened by the rain, the area of which surface is estimated by Mr. Schleiden at fifty times that of the ground. Another cause is the constant evaporation during the vegetation season by exhalation of the same leaves, which Mr. Lafosse estimates at 150 cubic meters per hectare and day; and, finally, the large quantity of heat lost through the fixation of carbon, which the same Mr. Lafosse, upon the data furnished by Messrs. Lecart and Parisel, estimates, per hectare and day, at so many calories as will melt a block of ice 316 cubic meters. On the other hand, these same quantities of water which the forests continually emit into the atmosphere must help to increase the degree of humidity of the parts which immediately surround them. Thus, while on the one hand the temperature is lowered, the humidity is, on the other hand, increased; and hence it appears to be quite a logical and natural conclusion that within the forests the point of saturation of the air must be reached more quickly and more frequently than in the open, and consequently rain will also fall more frequently and in greater quantities.
>
> This theoretical conclusion is borne out by abundant facts and experimental data.
>
> Mr. Riedel quotes the island of St. Helena and Lower Egypt. On the former, owing to reforestations effected on a large scale, the rainfall has actually been doubled since the times of Napoleon I; and in Lower Egypt, where in the eighteenth century rain only fell on from ten to twelve days in the year, the number of rainy days nowadays reaches from 30 to 40, since some 20,000,000 of trees have been planted. On the other hand, on the shores of the Mediterranean, in Syria and Palestine, there are numerous regions which were formerly in a flourishing condition, but have become to-day arid and waste in consequence of the destruction of forests.
>
> Mr. Ponti refers to the observations made at the Nancy school of forestry, which were confirmed in Russia by Professor Volsky, and by which it has been found that the rainfall in the interior of the forests was greater than outside of them. He adduces also the facts that in England, although it has not been possible to prove that the deforestation has caused here any reduction in the amount of rainfall or any appreciable change in the climate generally, it has been found nevertheless that the temperature is lower in forest-covered regions, the difference being as much as 3 degrees on the hottest days.

In regions where a considerable part of the precipitation is in the form of snow the forest catches it in the branches, protects that which falls to the ground from the sun, and retards its melting. These effects bear upon the proportions that evaporate or run off or sink into the ground and will come under those heads. It does not appear that forests influence the amount or distribution of snowfall.

Forests in relation to ground water.—Inasmuch as ground water and soil moisture are wholly derived from precipitation, any effect that forests may have in regulating rain extends to them. As compared with bare ground which receives all the rain and snow that fall, the ground beneath trees gets only a part, as they catch some proportion in their foliage. The percentage caught varies from 20 to 40 per cent of the precipitation measured in adjoining fields, according to the kind of trees, the density of stand, and other factors. Thus, if the conditions for percolation are the same under the trees and in the open, the earth under the forest receives less than that under the bare surface. An approximation to this assumption is reached on level plains, provided the soil in the open be in an excellent state of tilth.

---

[a] Permanent Intern. Ass. of Navigation Congresses. X Congress, Milan, 1905. Report by Cipolletti, C., on Deforestation, etc.

That proportion of the rain and snow which reaches the ground under the trees wets the mulch of mosses, leaves, and decaying wood, and such part as is not thus absorbed seeps into the ground below. Only a small part escapes as run-off, unless the slopes be very steep. The mulch of decaying vegetable matter is extremely absorbent and will hold as much as 50 per cent of its own volume, or two to three times its weight of water. From extended experiments in Germany with straw, leaves, and humus it appears that the moisture thus caught is evaporated to the air in dry seasons, and it would therefore be uneconomical from the point of view of ground-water storage to increase the surface litter beyond that required to prevent run-off. Under some conditions of forest maintenance it would probably be economical to keep the surface comparatively clean of litter and in an open state, such that the rain sifting gently through the foliage would be absorbed by the ground in a maximum degree.

The subsoil beneath the forest near the surface is moister than that beneath the adjoining fields. This is due chiefly to the covering of moist surface litter and to the relatively small evaporation at the ground surface. Deeper in the subsoil, at depths below a foot, the forest soil is often drier than that below the adjoining fields, for the tree roots take a large amount of water which is given off through the foliage. Thus, if we contrast the soil condition under the forest with that under the bare field we shall find the ground beneath the forest moister near the surface and drier below. The continuity of water films in the ground is a condition which promotes percolation, and the relatively moist surface layer thus aids the falling drops in reaching the deeper, drier layers when precipitation occurs. In the open, when the surface layer becomes measurably dried out and filled with air, a sudden rain may so occupy the pores of the immediate surface as to seal them against the escape of the underlying air, and the latter then prevents the percolation of water, and the impervious surface becomes one on which run-off is inevitable.

The total effect of trees in preventing some proportion of the rain from reaching the ground and in using some part of the moisture contained in the ground in their physiological processes is indicated by the depths to which they depress the level of ground water as compared with that in adjacent fields. Observations on this point have been made in Russia, France, and Germany, and the results are in agreement for European conditions. They were made on level ground, and the conclusions do not apply where run-off from the surface is copious. It is shown that—[a]

(*a*) The water table lies deeper below the surface under a forest than outside of it, if account be taken of the relief;

(*b*) The depression of the water table is more pronounced under old forests than under young plantations;

(*c*) The depression is more pronounced in dry climates than where there is much rain.

The amount by which the water table may be depressed varies from a fraction of a meter to as much as 3 meters. It is observed in the level steppes of southern Russia, where the rainfall is moderate, that springs are found outside of the forests rather than in them. In citing these results, it is important to insist upon the distinction to be made between level and sloping surfaces. A comparison of the ground-water level beneath the forest with that beneath a flat field in which percolation is at a maximum gives an entirely different result from a similar comparison, in case the surface is so inclined as to permit run-off from the bare ground.

According to very careful and accurate observations made in Switzerland from 1903 to the present time and still in progress, it is found that the run-off from a wooded watershed is but 60 per cent of that from a cleared watershed, all other conditions being the same; and that the maximum high-water level of the stream from the former is 30 to 50 per cent lower than that of the stream from the latter.

The same observations establish the reciprocal fact that there is a larger and more continuous percolation of water into the ground and steadier flow of springs during drought from the wooded watershed than from the cleared watershed.[a]

Forests in relation to evaporation.—At the surface of the soil moisture passes into a state of vapor and is carried away by the air; this is evaporation. At the surface of a leaf moisture is given off by the living organism; this is transpiration. Evaporation is a physical phenomenon which increases with the dryness, temperature, and movement of the air; transpiration is a physiological phenomenon which depends upon the kind of plant and its response to the conditions to which it is exposed. Evaporation from the soil draws upon the moisture contained in the capillary spaces between the soil grains and extends down to the point where the soil is saturated—that is, to the water table in humid regions, or in arid regions to the point where the subsoil is so dry that the capillary films are no longer in contact. It continues until the available moisture in the soil is so reduced that the tension of the films about the soil grains becomes great enough to resist the tendency toward vaporization at the surface and evaporation then practically ceases, although diffusion into the air spaces of the soil continues even at some depth. Transpiration from the surface of the leaf responds in some measure to sunlight and shadow, to humidity and dryness, and to temperature. Among these humidity is the most important. The rate of transpiration is, however, subject to physiological regulation, the mechanism of which is not understood. In certain experiments conducted by the desert laboratory it was found that in plants under examination the water loss due to transpiration was checked at temperatures above 79° F., whereas the checking action disappeared at lower temperatures.[b] Thus, some plants possess a means of defense against excessive transpiration during hot weather and drought, whereas the inert soil must go on yielding moisture almost to the last atom.

[a] Engler: Der Einfluss des Waldes auf den Stand der Gewässer. Centralblatt für das gesammte Forstwesen, Jan., 1907, pp. 35–40

[b] MacDougal, D. T.: Botanical features of North American Deserts. Carnegie Institution, Publication 99, 1908, p. 86.

There is a certain amount of evaporation from the leaf surface, but it is exceedingly slight. It differs from transpiration in that it takes place through the tissue itself, whereas transpiration occurs through the stomata. A grape which has no stomata gives a good illustration of the very small amount of evaporation from such surfaces.

Underneath the trees in the forest the conditions are much less favorable to evaporation from the soil than in a bare field near by, the humidity being higher and the temperature very much lower. Above the trees also the air is cooler and more humid than it is at the same altitude above bare ground. This last statement requires some explanation. Sunlight passing through the air raises its temperature somewhat, but a more important influence is that of the currents of air set up by contact with the surface upon which the sunlight falls. We all know the heat which rises from bare ground, and how comparatively cool is the sward. Similarly the surface of the ground is hotter than the surface of the foliage of a forest. The effect of radiation from these two contrasting surfaces is shown by the experience of French aeronauts to extend to a considerable height. According to E. Henry:[a]

> The cooling effect observed by æronauts in passing over forests of a certain extent is indicated by a marked descent of the balloon. It is a well-established fact that this effect was experienced by a number of military balloonists above the forest of Orleans, the balloon being at an altitude of about a thousand meters. It appears to be demonstrated by the balloon ascensions made up to the date of the statement that the influence of forests of similar extent (34,000 hectares, or about 20 square miles) is observable up to an altitude of 1,500 meters.

To sum up the preceding considerations: The effect of these complex relations has been made the object of investigation, particularly in Germany, through the study of the amount of moisture remaining in the soil under the various kinds of trees, and in the adjacent open. Some reference to these results has already been made; but the general conclusion is that the effects of transpiration from luxuriant foliage are very materially greater than those of evaporation from the bare level surface.

The most striking illustration of this factor is the effect of eucalyptus trees, which, planted in the Pontine marshes near Rome in 1870 (in the vicinity of the Convent of St. Paul of the Three Fountains), have lowered the level of the ground water several decimeters. In this case the transpiration from the water-loving eucalyptus is more vigorous than was the evaporation from the water and vegetation of the swamps.

The relation of the forest to run-off on level lands is not an important factor. As we have already seen, it is possible to keep level fields in such a condition of tilth that the amount of run-off from them is no greater than that from the forest. On slopes the case is different.

---

[a] Henry, E.: Sur le rôle de la forêt dans la circulation de l'eau à la surface des continents. Comptes rendus du Congrès des sociétés savantes en 1901.

The effect of the forest is, first, to diminish the violence with which the rain strikes the ground and compacts it, for the drops are checked by the foliage. They fall from branch to branch and reach the ground with greatly diminished momentum and in a finer state. That portion which drops from the leaves comes in larger masses, but still gently. Beneath the forest the rain finds a moist soil whose capillary water is capable of vigorous downward circulation. The soil is also opened by the forest roots, and being protected from the compacting and cementing influences of a free exposure is decidedly porous. All these conditions militate against run-off and promote absorption. In consequence the run-off from forest areas gathers slowly as compared with bare slopes, and the ratio becomes increasingly favorable in regard to forests as slopes become steeper. This fact enters into the consideration of the value of forests in mountain regions as compared with those on plains. Ebermayer,[a] from whose paper many of the data used in this report have been taken, says:

> In view of the exact investigations which have been cited above, and which extend through thirty years, it is no longer possible to maintain the assumption so generally made, that forests increase the amount of ground water and constitute a storage reservoir for the supply of springs, *at least not so far as plains are concerned*. The draining effect of the forest is, on the contrary, so great that a much greater supply of water gathers in the depths beneath a treeless plain than beneath dense woods, provided that the underground conditions be the same in both cases. It follows that under these conditions the discharge of springs is not increased, but lessened, by woods. *Decided emphasis must, however, be laid upon the fact that these conclusions hold primarily only for the plains, and are not to be extended inconsiderately to uplands and mountains.* Although the influence of the woods upon soil, moisture, percolation, and ground water under like conditions must be the same in mountains as it is in lowlands, and only moderate differences are likely to appear, nevertheless the forest on the mountain differs very decidedly from that on the plain in regard to water control, inasmuch as in mountain regions, in consequence of the surface run-off of rain and snow water from the slopes, a factor is introduced through which wooded mountain slopes receive a much larger amount of water than bare, unwooded watersheds.

Forests in relation to erosion.—The emphasis which Ebermayer lays upon the loss through run-off from bare slopes is in no sense exaggerated. The detrimental character of this loss in relation to storage of water for all the activities of civilized communities, including navigation, can not be exaggerated. Its effects have already been described in speaking of flood run-off, but we may here recur to the injury which it does, particularly with reference to the erosion of soil. If it were conceivable that we could adjust our activities to the loss of one-half of the available water through flood run-off it would still be inconceivable that we could permit the accompanying loss of the soil. Without soil the earth becomes a desert. Without soil man must cease to exist.

This consideration is of prime importance everywhere, but it assumes overshadowing importance beyond any other in mountain regions of large rainfall. The Appalachian Mountains constitute such an area of great extent and of very marked character, and they occupy a very critical position in the center of the richest half of our country. Concerning the effect of uncontrolled run-off from this region we have, unfortunately, abundant evidence, the emphatic testimony of ruined and abandoned lands.

---

[a] Ebermayer, Ernst: Einfluss der Wälder auf die Bodenfeuchtigkeit, auf das Sickerwasser, auf das Grundwasser, und auf die Ergiebigkeit der Quellen. 1900, p. 38.

Summing up the observations of the thoroughly qualified and unbiased observer, L. C. Glenn, we are able to show what relation the destruction of the forest bears to run-off in the watersheds of the southern Appalachians.

Forty-six creeks and small rivers, whose watersheds may be described as timbered rather than cleared, are known, according to observation and local repute, in times of flood to rise gradually, to continue high for several days, and to subside slowly. They carry but little sediment, and they maintain a good volume of water during dry seasons.

Thirty-eight creeks and small rivers in the same watersheds, whose slopes may be described as cleared rather than timbered, are known, according to observation and local repute, in times of flood to rise rapidly to extreme flood height, to carry excessive quantities of mud, sand, and gravel, and to fall quickly. In dry seasons they are very low, and the range from lowest to highest stages has increased and inflicted much damage in very recent years.

Two other classes of conditions may be recognized in Professor Glenn's descriptions: The one, of valleys still timbered, but which are being damaged by beginning of logging and particularly by erosion of logging chutes; the other, of watersheds that are largely cleared but grassed, and which the grass protects from erosion, though not in the same degree from rapid run-off.

Such evidence as this, collected by a qualified and impartial observer with reference to individual watersheds, establishes for the region in question, comprising the mountains of North Carolina, Tennessee, and Georgia, the fact that forests exert a beneficial influence on stream flow by storing the waters from rain, preventing their rapid rush to the streams, and paying them out gradually afterwards, thus acting as true reservoirs in equalizing the run-off.

These detailed observations sustain the general facts which every mountaineer knows: That streams which flow from a forested area rise slowly, carry little sediment, and fall slowly in times of flood, and throughout the year are relatively far more uniform in their flow, whereas streams which flow from deforested regions rise quickly, carry heavy bodies of sediment, and sink early in the season of drought to minimum low-water stages.

On the basis of superficial observation it is sometimes said that deforestation as it is now proceeding in the Appalachian Mountains does not seriously affect the streams, because the forest which the lumberman cuts is soon replaced by an aftergrowth. It is true that the full effect of deforestation follows immediately upon lumbering only in extreme cases, but wherever the forest and the superficial forest soil are removed a beginning has been made in the process of erosion which will ultimately remove all the soil. The aftergrowth that follows the severe cutting and burning under modern lumber conditions is a weakened growth. It never covers the surface as the virgin forest did; the surface is always traversed by freshly cut gullies, and the level of channel grades is sunk below it from a few inches to 10 feet or more. The advantage thus given to the eroding power of thousands of rills is not overcome by any natural process. Man alone can so direct and localize a defense as to make it effective, and he does it only at great cost. It is true that under favorable conditions the soil will maintain itself till the trees of the aftergrowth become merchantable timber, and that the processes of cutting, burning, and partial erosion might under the most favorable circumstances be continued till several crops had been cut from the surface and a half a century or more had passed, but the result would be deferred merely. That result is to be seen in the bare mountains that stretch from Spain to Asia Minor and in those of northern China.

The forests have long protected the Appalachian Mountains; they were growing throughout the eastern United States when a great plain stretched unbroken from the Atlantic to the Mississippi, and they have continued their growth, though changing in species and in distribution, while the earth's surface has been raised to the heights from which the mountains are being carved. During the whole process the forests have conserved and protected the mountain slopes from washing.

Let us pause to consider the slow changes of the ages that preceded the advent of man, the destroyer—or possibly the protector.

On a vast plain covering the area of the eastern United States and Canada there grew a luxuriant forest. The plain was almost continuous. A few broad, low hills rose from it where now are North Carolina and eastern Tennessee. In the forest grew the tulip tree and the magnolia, along with many species that are now gone, but the modern oaks were not yet developed.

Within the earth titanic forces gathered gradually till their power sufficed to raise the surface slowly and to elevate the plain. Rising in a zone that reaches from Canada to Alabama the elevated plain became a plateau from which many rivers flowed to the Atlantic and Pacific. As the slopes steepened, the waters, falling swiftly, cut their channels deeply and made canyons, which widened to valleys. Genial climates favored vegetation, which during the long, slow process of mountain growth and valley carving never was removed extensively. Woods prevailed and held the soil, always adjusting their growth to the very gradual changes of the valley slopes. If perchance a steep was bared by a sudden landslide, it was in time washed clean to the hard rock and became a cliff, or caved and extended till vegetation could take a foothold again. Thus the mountains of to-day were slowly carved from the upraised mass, and ever through the ages the forest trees grew and flourished and died, generation after generation, in the soil their roots held fast and enriched and deepened. It was their destiny to outlive the mountains, whose inert mass must yield eventually to the unceasing attacks of erosion and be worn down again to a gently sloping plain, over which the forest should stretch its living covering. But man has come, he holds the forests' destiny in his hands, and his own is intimately linked with theirs.

CONCLUSION.

The effects of rainfall in critical regions are not beyond man's control.

The methods of control are incident to agriculture, grazing, and forestry, and their application pays in larger crops, better feed, and

bigger cut per acre, as well as in national welfare both present and future.

The circulation of water in the streams, like the circulation of blood in the veins, carries the effects of negligence or care through the whole body of the commonwealth.

Every farmer, herdsman, lumberman, and landowner is morally responsible to his community for his influence on waters and their effects, and should be held to that responsibility by his conscience, by public opinion, and by law.

METHODS WHICH SHOULD BE ADOPTED BY PRIVATE OWNERS TO INSURE THE PERPETUATION OF OUR TIMBER SUPPLY.

By C. S. CHAPMAN,
United States Forest Service.

IN GENERAL; METHODS TO BE ADOPTED.

The best available statistics show that in the United States the annual cut of timber is from three to four times as great as the annual growth. This fact is conducive to conjecture as to the timber supply of the future, and as to the measures to be taken to prevent a future shortage with its inevitable depressing effects on the business and development of the whole country.

Steps looking to the perpetuation of our timber supply, so far as private owners are concerned, must be along two broad lines:

1. Aid by the Federal Government and by States to private owners by legislation and assistance, making it possible for private owners to successfully and profitably practice forestry.
2. The actual practice of forestry by corporations and individuals, which alone can increase the productiveness of forest lands and insure a future supply.

These two subjects are so closely connected that one can not be treated without, to some extent, touching on the other.

IMPORTANCE TO COUNTRY OF PRIVATE HOLDINGS.

The most liberal estimate of the wooded area of the United States, that of the Geological Survey, places it at 700,000,000 acres, while others have placed it as low as 500,000,000 acres.

Of the amount estimated by the United States Geological Survey, there were on July 1, 1908, 156,082,756 acres in national forests, and 2,582,711 acres in state holdings. This leaves the area of woodland held by private owners, or which will probably pass into their hands, 541,334,533 acres, or over three times as great an area as is held by the Government and States combined. If this area represents its proportion of the timber cut of the United States, which is a fair assumption, three-fourths of the timber supply is on private lands.

It is evident, therefore, that no matter what measures are taken by the Federal Government and by the States to properly manage their forest lands, unless the great area held by individuals is properly cared for the future timber supply is far from being assured.

Since the annual timber cut of the United States is from three to four times as great as the annual growth, the situation will not be satisfactory unless, under forest management, timber can be made to grow from three to four times as rapidly as at present. A similar situation has been successfully met in other countries and undoubtedly can be in the United States.

There are at the present time, both in the hands of private individuals and of the Government and States, large tracts of land which should and will be planted. Lack of authoritative data makes it impossible to say how much land there is in the United States which does not now but would support forest growth and yield better returns from a forest crop than from any other. Combining the treeless areas of the West, the cut and burned-over lands of both East and West which are not restocking, and the land put to some kind of agricultural use but best adapted to the growth of timber, the area is emphatically worthy of consideration in connection with a national timber supply. It is, of course, true that much land now in forests could serve its highest usefulness as farm land and that, with the increase of population and with better and more intensive methods of farming, land not now considered of any value for agriculture will be used for this purpose.

It is certain, however, that this enlargement of agricultural areas to include land now forested can not permanently exceed the amount of treeless areas that should be planted, so that eventually the forest-covered area of the United States should be at least no smaller than at present. Even this means intensive forest management if the United States is to furnish its own timber supply. Economy in use and the extension of preservative treatment of timber will also serve to aid in the perpetuation of the country's supply of wood.

AID TO OWNERS OF PRIVATE TIMBER LANDS.

Many private timber holders are now practicing forest management of some nature. Exactly how many, it is impossible to say. (See Tables I and II.) A mention of the work done by the Forest Service to assist private holders will give a general idea of the interest taken. Up to June 30, 1908, at the request of owners of woodland, 568 examinations of tracts were made by trained foresters of the Forest Service. The number of cases where assistance was asked and could not be given was large. The area affected by the examinations was 10,280,783 acres, in 41 States and Territories.

In a number of cases detailed working plans were made for the conservative management of the timber tracts. Much of the cost of the work was at first borne by the Forest Service, for the purpose of stimulating interest in forest management and to secure necessary data for the Government on the growth of trees, their silvicultural characteristics, and best means of management. At present, however, the owners of woodland must bear the greater part of the expense themselves, except in rare instances where the preparation of a plan would be of unusual educational value, or when a plan has never been made by the Service in the region.

In April, 1907, the Forest Service sent out a circular letter to 100 owners of small timber tracts and to 402 owners of wood lots, requesting them to make a statement of the work done on their lands as a result of recommendations of the foresters who examined their tracts. To these letters 152 replies were received, showing that 102 were carrying out the recommendations of the Service. Twenty-one reported some work in progress and 29 had done nothing. If this may be taken as a fair sample, more than 450 of those who have received aid from the Federal Government are now practicing forestry, at least to a limited extent.

Up to June 30, 1908, 452 persons received actual help on the ground in forest planting affecting nearly 64,000 acres. In addition a large number of people received aid through correspondence. About 32 per cent of the plans made were carried out either wholly or in part.

In addition to the aid given by the Forest Service a number of States have given, through their state foresters, valuable assistance at small cost. Notable among the States well equipped to do this work are Connecticut, Massachusetts, and California.

Also, the publications of both federal and state governments have aided private owners very greatly by giving valuable information on the handling of natural forests and on forest planting.

Laws have been passed in nearly all States to prevent forest fires and other sources of forest destruction. Twenty-six States have boards or commissions whose whole or partial duty is to look after forest matters of the State, and nine of these States have state foresters. Twelve States have tax-exemption laws in some form, and several others offer rebates and bounties. There are still some States which have shown little interest and have not considered forest preservation a question of sufficient importance to warrant the enactment of laws to help their citizens.

PRIVATE FORESTERS.

As yet there are not many foresters in private employ. A few lumber companies are now employing them, and a few firms of consulting foresters are at work. The best figures attainable, however, do not show over 70 private foresters actually doing professional work or teaching.

While the interests of both Government and State make it desirable that necessary aid be given those who apply, advice on the ground and plans for caring for timber land should more and more be done by the private forester. As large companies become really interested in forest work and take it up as a business proposition, they will secure the services of trained men. As soon as the practice of forestry becomes accepted as good business policy there should be an end to the great duties of State and Federal Governments as disseminators of knowledge and stimulators of forest preservation through aid other than by legislation, and then the field can be left very largely to private foresters.

THE PRACTICE OF FORESTRY BY OWNERS OF TIMBER LANDS.

Owners of timber land may be broadly classed as—

(*a*) Those who purchase for speculation and hold for a rise in stumpage prices;

(*b*) Those who hold for game or pleasure preserve and not for profit;

(*c*) Those who either hold to supply their mill, to furnish logs for market, or to furnish fuel, posts, and other necessary timber either for home use or for sale.

Those of the first class obviously do not cut their timber, and aside from necessary protection from trespass and fire which might result in financial loss they are not interested in any form of forest management.

Those of the second class will and generally do practice forestry if it will foster any of the purposes for which the forest is held; and as forest management may mean money return without lessening the beauty or value of the forest, the owners are generally favorable to forest management. A forest of this class is that owned by the Blue Mountain and Forest Park Association in Sullivan County, N. H. This tract, which contains about 15,090 acres of woodland, is held by the owners as a permanent game preserve. Under forest management it is possible to so care for the tract that its usefulness as a game refuge is not interfered with, and at the same time a considerable revenue from the sale of timber is secured. The tract has been managed by a forester since 1904.

The third class of owners hold their land for profit, direct or indirect. This is by far the largest class and the one on which the future timber supply of the country must rest. Forest management, unless it shows good financial returns—better returns, in the long run, than under present methods—has no attraction for this class of owner. This is only natural. Many of the large holdings are owned and worked by stock companies, to secure profit on their investments. If forest management can not show a profit to this class of owners it will not be practiced. If it can show profit and this class of owners can be led to see its advantage, they will adopt it. It is therefore very important that every possible measure be taken by the Government, by the States, and by private owners to determine the proper management of timber lands in different sections and ascertain the profits and benefits to be derived.

One great drawback to forest management by private owners has been the ordinary attitude toward a timber tract. It has been formerly and is still often looked upon as a source of supply which when cut over is gone for all time; and the possibility of continuous crops is not thought of. In the case of a manufacturing plant the attitude is quite different. The company putting up a large and expensive saw or paper mill that costs from fifty thousand to several million dollars plans to have this plant run for a sufficient number of years to warrant the investment. If a supply of timber to last through this period is not already owned, the possibility of purchasing material is carefully calculated, rather than the possibility of growing a second crop. In the past it has been profitable to cut over a tract without regard to future crops, and then with the profits to purchase another tract to be treated in the same way. This practice has had extremely disastrous results, for it has left cut-over areas in a condition which it will take years to correct, and made it possible to so increase the output of lumber when prices are good that overproduction and a resultant market depression ensues.

One great argument against forest management is that because of fluctuating prices safe calculations of values can not be made a long time in advance. In older countries prices of forest products are more stable and the crops can be harvested each year in accordance with an annual or periodic production of wood. With varying prices there is a decided tendency to over-cut whenever prices are high and hold when they are low. This, of course, interferes with systematic forest management. However, stumpage is becoming more valuable, timber land more and more is getting into the hands of large companies who will hold for a second crop, and as it becomes more difficult to buy another tract from the profits of the one cut over, cutting with a view to a second, a third, and succeeding crops on the same land must result.

HOW SHALL PRIVATE TIMBER TRACTS BE MANAGED?

It is extremely difficult to say how private timber tracts should be managed. In a country that varies so greatly in climate, topography, variety of species, and market facilities, what is good management for one tract becomes bad for another; and the problems become so local in application that it is conceded by foresters that each tract must have its management prescribed after a careful examination on the ground. The application of general rules for the management of tracts in various parts of the country is impossible, and it is equally impossible to give information in a single report. Moreover, any information given would be of necessity too general to be of much real value. The Forest Service has issued publications on the management of woodlands in various sections, and some of these are given as references to any timber-land owner within a region specifically covered. Modifications will, of course, have to be made to suit individual conditions. Many other works on forestry have been published, and anyone desiring information on forest management can easily secure such information from some of the publications of the Forest Service.

List of some of the publications of the Forest Service containing valuable information regarding forest management.

Circulars.—No. 6, No. 54, No. 22, No. 55, No. 109, No. 37, No. 61, No. 45, No. 99, No. 145, No. 41, No. 100.

There are certain fundamental rules which must, of course, be followed in the practice of forestry everywhere. Timber must not be cut faster than it is produced, if an equal annual or periodic yield is desired. If reproduction is to be secured through natural means, young growth must be cared for. A tract must be at all times guarded against destruction by fire and insects. Waste in logging must be avoided. Unless restocking is to be by planting, the basis for a second crop must be left on the ground either as seed trees or young growth. Often the mere prevention of fire will in itself result in a good growth of young timber.

A number of large timber-land owners are now practicing forestry. Some of these are C. F. Craig Timber Company, West Virginia; Delaware and Hudson Lumber Company, New York; Cleveland Cliffs Iron Company, Michigan; and Pennsylvania Railroad Company.

All of these companies employ foresters. In addition there are others who, though they do not employ foresters, are doing something to protect their land and grow a second crop. The Santa Clara Lumber Company, of New York, while not engaged in systematic forest management, is leaving a considerable amount of timber standing, and is planting skid roads and other open places as soon as an area is logged over.

In the August number of the Southern Industrial and Lumber Review there is a very interesting article on the practice of forestry by lumbermen in the pine belt of Texas. The company that publishes this journal sent out a number of letters to prominent timber holders and lumber manufacturers in Texas and asked if they had any plans for conserving their timber or reforesting their cut-over land; if any attempts toward these ends had been made, and, if so, with what success. The Journal states:

> In the first place, practically all of the lumbermen declared themselves unconditionally in favor of any fair plan that could work for the insuring of future forests could such a plan be discovered. None of them advanced a feasible plan for securing such an end, and it is safe to say that no human being in all this public discussion of the matter has yet advanced a practical plan whereby the objects desired could be attained.

Three of the firms written to were taking measures to conserve their timber, and others wrote that they intended to do so in the near future.

The Southern Industrial and Lumber Review draws the conclusion from the answers received that one of the cogent reasons why forestry can not be practiced is that taxes are excessive. Its publishers also believe that if timber lands were exempted from taxation until the crop is merchantable it would be a great stimulus to the practice of forestry.

It is interesting to note that the trade journal quoted considers that no feasible plan for the management of forest lands in the Texas pine belt has been set forth. More than most regions this section has been studied by foresters, and their conclusions and plans for managing various tracts are of record. The trouble is that while many timber-land owners are now holding their land for future crops (see Tables I and II) few are doing more than this. An expenditure whose returns will show only after a long period is not considered seriously, and any plan for forest management entails a certain amount of expense. Timber-land owners, for the most part, demand a system of management which brings good results without extra expense to the business or any inconvenience in logging. Such a system is possible only in very rare instances.

Table I shows the results of inquiries to 3,629 lumber and coal companies for information about fire protection and the policy toward cut-over holdings. To these inquiries 1,331 replies were received, and of this number only 639 contained information complete enough to be tabulated.

This tabulation, which covers 24 Eastern States, shows that of a total area of 3,512,846 acres, 1,764,609, or practically half, is held for future crops, and if not now receiving some protection and care for the future, presumably will, eventually. It shows, too, that not all of the land held for a second crop is protected from fire.

It is also of interest to note that, while not quite 50 per cent of the land is held for a second crop, exactly half of the owners are holding their land for this purpose.

Table II shows the results from 2,089 schedules of inquiry send to members of lumber associations. Many of these had sold their land or were not actually operating ~~in the~~ woods, so only 596 satisfactory replies were received. This table, unlike the first, is compiled from replies from both Eastern and Western States. In all, 35 States are represented, and the interest shown in all sections was particularly good. Of more than 13,000,000 acres represented, nearly one-fourth was being held for a second crop, and a slightly greater amount was being protected from fire.

One of the questions asked in the schedule was:

> What method of conservative forest management do you consider practicable in your section from a business standpoint?

A number of interesting replies were received.

The Rietbrick Land and Lumber Company, of Wisconsin:

> As stated, no timber 10 inches and under in diameter is cut. By taking out older trees it gives a chance to younger trees for better growth. We expect to harvest these logs in, say, possibly fifteen to twenty years. We are giving consideration to young and thrifty timber on cut-over lands with a view of future crops. We have done this for several years, before which time it was not considered.

The Eel River Valley Lumber Company, of San Francisco, Cal.:

Replanting redwood lands has been initiated to a small extent. Eucalyptus is being put out to a very limited amount. We planted last spring about 500 trees of the blue variety as an experiment. These trees were planted when about 1½ to 3 feet high on old logged-off land on a steep hill, where they were exposed to all the heat of summer and to the rain and storms of winter. No special attention has been paid to them, as it is desired to see what they will do on such land without special care. There is no water in the surface where they were set out. They have shown a strong, vigorous growth during the summer, and about 75 per cent have lived.

The Desert Lumber and Coal Company, of Arkansas:

Trees should be cut up to 12 or 14 inches diameter, younger trees left standing, and tops of trees cut should be burned up carefully; this would perpetuate our forest indefinitely.

The Conway Lumber Company, of Horry County, S. C.:

Cut no timber under 12 inches in diameter, 18 inches from the ground. Protect the small trees in cutting the big ones, and keep fire out of the forests.

The C. R. Cummings Export Company, Liberty and Harris counties, Tex.:

We cut only the larger timber and leave all small timber standing, cutting principally 12 inches and up in diameter.

The Shaw Land and Timber Company, of Tidewater, Va.:

None necessary except keeping out fire; do not cut the small timber; nature does it all in this flat country.

William Brown & Sons, of Worcester County, Mass.:

We cut off timber clean excepting a few seed pine, sowing to pine seed and reseeding from old pine trees.

Mr. Joseph H. Elliott, of Windham County, Conn.:

My method is to cut out everything ready for market and leave every small tree. The trees that are left grow faster, and in a few years another crop is ready for market.

Throughout the answers to the schedule, complaint is made of the high tax on forest crops, and legislation is suggested to lessen the burden of the owners in this respect. A number of the answers also suggest stringent government rules, accompanied by inspection, that will require private owners to leave a certain amount of timber on the ground when logging and require them to protect from fire. Several advanced the idea that the Government should buy cut-over land and hold it for a second crop, as the expense to the individual was too great.

In a large number of cases companies appear to be holding land for a second crop and, in addition, are endeavoring to keep out fire and to leave some timber on the ground. This is, of course, a very crude method of management, but in many instances it will no doubt result in the owner securing a good second crop and is an excellent indication that more intensive management will follow.

IS FOREST MANAGEMENT BY PRIVATE OWNERS PROFITABLE?

Whether or not forest management is financially successful depends almost entirely upon local conditions. It often happens that the value of a forest is indirect, but ordinarily, with fair market facilities, any tract can be so managed as to produce revenue. There is no question but that forest management pays on the farm wood lot, which is managed to supply the farm with fuel, posts, etc., and from which the farmers can cut a few ties or telephone poles for the market during a time when the farm work is dull, and thus derive a small revenue as well as have a means of employment.

With the owner who keeps his woodland as a game preserve, or as a playground for guests stopping at his hotel, or as protection to a watershed, and who would under no circumstances allow ordinary logging to be carried on within his holdings, a system of forest management adapted to the needs of the case is the only feasible plan. Any revenue derived is of course just that much gain, for, otherwise, no cutting would be allowed.

To the mill man or logger who is getting out his product to compete with others in the same business, any management which adds to the expense is questionable. It is evident that in most cases forest management adds to the cost of logging. It means marking the timber to be cut out or that to be left as the case may require; it means a lighter cut on the same area than would be the case under ordinary logging practice; it means greater care in felling to avoid injury to growth left for a second crop; it means care that fire shall not start; and it also means as complete a utilization of the tree as possible. In return it makes of a sawmill or paper mill plant a permanent investment, provided the owner has enough timber land to produce yearly an amount of timber equal to the annual consumption of the mill. It enables the owner to carry on his business without fear that high stumpage prices will force him out, for in raising his own timber he makes the cost considerably more constant. He has at all times on his land a valuable crop on which he can realize, instead of a cut-over area valuable only for pasture, or, in some cases, for which a small price may be secured for agricultural use. The small value placed on cut-over land is best shown from the fact that forest lands carried on the delinquent list in Michigan comprise 6,000,000 acres, and in California over 500,000 acres. In Wisconsin very large forest areas have been forfeited for nonpayment of taxes, but in 1907 the legislature authorized the purchase of such land for State forests. These forest lands are not worthless; they will in time yield timber again. They were allowed to revert to the State because their owners considered that being unprotected and subject to high tax they could not be held at a profit. Whether or not it would pay to plant these lands under present conditions is questionable, but if properly cut, so as to secure reproduction by natural means, they would probably have shown returns, even at an expense for fire protection and high taxes.

The profit to be derived from lands managed under forest principles has been carefully worked out in a number of specific cases by the Forest Service. Yet returns depend so largely upon the increase in stumpage price that figures of future returns are only conjectures.

The care of wild woods in the East will in nearly every case, by the use of very conservative figures, show a 5 per cent investment on the value of land and the cost of maintenance. If the value of stumpage at the end of the rotation exceeds the estimated value, greater returns will, of course, result. The following figures are quoted from Forest Service Bulletin 64, United States Department of Agriculture, Loblolly Pine in Eastern Texas:

> In the following computation estimate must enter to a considerable extent, but from the tendency of lumber prices to advance it is apparently safe to assume that, after forty years, tie stumpage will be worth 8 cents and lumber $2 per thousand. The yield of the forest may easily be more than the first crop, because it will be cared for and because the area of prairie is steadily lessening, but it will be safest to count on the same yield after forty years as is obtained now.
>
> *Estimate of outlay and returns per acre in holding cut-over loblolly pine land for a second crop.*
>
> OUTLAY.
>
> | | | |
> |---|---|---|
> | Cost of land | | $0.50 |
> | Interest on same at 5 per cent | $0.025 | |
> | Taxes, at 1 per cent of value | .005 | |
> | Cost of management | .050 | |
> | Annual charge | .08 | |
> | This 8 cents paid annually for forty years, and with compound interest at 5 per cent amounts to | | 9.66 |
> | Total | | 10.16 |
>
> RETURNS AT END OF FORTY YEARS.
>
> | | |
> |---|---|
> | 80 ties, at 8 cents each | $6.40 |
> | 2,500 board feet of lumber, at $2 per M | 5.00 |
> | Land will sell for | 1.00 |
> | Total | 12.40 |
> | Less outlay | 10.16 |
> | Net profit | 2.24 |
>
> This shows a 5 per cent investment with a margin of $2.24, or a net return of a little less than 6 per cent on the outlay. There is little doubt that this rate can be considerably increased in many cases, because all the figures used are conservative. If ties are cut more carefully, for instance, it will be possible to get at least 10 more from each acre, which means 80 cents, and increases the return on the investment to 6 per cent.
>
> Other elements of this question are too problematical to be set forth in figures with safety, yet they deserve to be considered. First, the forests of eastern Texas are nowhere as dense as they might be, and it will require only a little care to increase the average stand from about 140 trees to the acre to at least twice that number. In addition, the actual forest-bearing area can be increased by reclaiming the marshes which now form so large a part of the region that the actual forest yield in these calculations is one-third of what it might be. Second, the tie supply must be kept up, and a plan which promises to do it while paying upward of 5 per cent compound interest is worthy to form part of the maintenance system of the railroads which are interested in that section.

But the best proof that forest management pays is secured from timber prices abroad, where every country but Turkey and China manage their timber lands in accordance with forest principles. In Prussia in 1904, the net return from forests was $2.50 per acre; and this is nearly ten times what it was sixty years previous.

In Saxony the net yearly revenue from forests is $5.30 per acre, the yearly expense $3 per acre. The following table is taken from Forest Service Circular 140, What Forestry Has Done. It shows what has been done by governments, states, and communities; and there is no reason why tracts held by private owners should not do equally as well as government holdings.

What forestry has done in other countries shows, first of all, that forestry pays, and that it pays best where the most money is expended in applying it. Both these points are very clearly brought out in the following table:

Expenditures and revenues of national forests, showing increased productiveness under larger expenditures.

Country.	Total net revenue from government forests.	Expenditure per acre.	Net revenue per acre.
Wurttemberg	$3,098,428	$2.05	$6.60
Saxony	2,299,000	3.00	5.30
Baden	829,102	3.58	4.42
Hesse	744,209	1.25	4.29

United States (1906-7)	128,650	.0093	.00086

FINANCIAL RETURNS FROM PLANTING.

The financial results to be obtained from planting depend very largely upon the locality and market. In sections of the country with ample rainfall and extensive natural forests, and where natural reproduction can be secured, it will not, for the present, pay to plant. Where timber is in great demand for all purposes and the natural forest is limited in extent, planting often pays extremely well.

For example, in Forest Service Bulletin 37, The Hardy Catalpa, the following returns are figured for some of the plantations examined:

	Net return per acre.
Hannewell plantation, 18 years old	$14.78
Munger plantation, 13 years old	15.01
Farlinger forest, 21 years old	12.65
Yagge plantation, 12 years old (yearly)	7.25–21.55

These plantations are all in Kansas and the returns shown are those for each acre each year.

In Forest Service Circular 145, Forest Planting on the Northern Prairies, the following statement is made:

> A single row of cottonwood trees planted 4 feet apart along the public highway has been known to produce 46.9 cords of fuel per mile in seventeen years. At $5 per cord this would have a total value of $234.50, or an average annual value of $13.80.

In the same circular the following statement is made in regard to white willow:

> For this age (twenty years) cottonwood groves average 560 trees to the acre, and yield 3.56 cords of wood a year, while white willow has 1,700 trees to the acre, averaging 3.42 cords. From this comparison it will be seen that what cottonwood gains in rate of growth in the individual trees is more than com-

pensated for in white willow by the larger number of individuals to the acre. As a lumber tree the former produces an annual net return per acre of $10.57. As a post tree, the latter produces a net return of $24.01.

And with regard to Scotch pine the following statement is made:

The maximum annual height growth attained in any one grove of this species was 3.75 feet and occurred between the age of 7 and 8 years. The trees were as high in two of the groves measured at 15 years as in another grove at 21 years. The difference in growth seems to be accounted for by the difference in character of the subsoil. In the former two it is sandy; in the latter it is loam or clay. The yield for the Scotch pine groves is estimated to be equal to an annual net return of $13.35 upon the upland as against 13 cents in boxelder, $1.71 in green ash, $0.61 in silver maple, and $2.21 in cottonwood.

Table III gives a comparison in rate of growth and yield between our available data and those for the same tree grown from the best quality of soil in European forests:

TABLE III.—*Height.*

Age.	American.	European.	Difference.
	Feet.	*Feet.*	*Feet.*
5 years	3.1	3.1	
10 years	13.3	7.9	5.4
15 years	24.4	16.2	8.2
20 years	31.4	25.4	6.0

TABLE III (*a*).—*Yield in cubic feet per acre.*

	Age.	Cubic feet.
	Years	
American	17	2,628
European	20	2,349
Difference		334

This table, while very incomplete, tends to show that, grown in America, Scotch pine 17 years old yields 334 cubic feet more per acre than the same species at 20 years of age when grown in Europe, assuming, of course, that soil conditions were the same in both cases.

In Forest Service Circular 81, Forest Planting in Illinois, the results of a study of a large number of plantations are given:

Hardy Catalpa. A 20-year-old plantation had material on it worth $449.50 per acre.

The material on a plantation of European larch 30 years old was valued at $386.31 per acre.

A 49-year-old black walnut plantation was valued at $396.72 per acre.

A 35-year-old silver maple plantation was valued at $96.74 per acre, and other plantations showed good returns on the investment in land and the cost of starting the plantation.

In general, it can be said that forest management as an investment will pay under ordinary conditions of market and in sections where forest growth is fairly rapid. The experience of older countries proves that it pays extremely well. With wild woods in this country it is often possible, by keeping out fire and by using a little care in logging, to insure a second crop on land which would otherwise be sold at an extremely low figure or revert to the State for nonpayment of taxes. Every lumberman is willing to assume that stumpage prices will increase, and timber is bought in large quantities with this end in view. This makes it advisable to grow as well as to buy timber to hold for future supply.

In planting the same is true. Land of little or no value can be made to yield good returns. A forest crop needs little attention and only a small outlay after the initial cost of starting. A farmer or lumberman can therefore with slight effort start a future crop which will then very largely look after itself. Forest planting has not yet secured the attention due it, not only as a necessity—if our timber supply is to be perpetuated—but as a profitable investment to the farmer or timberman.

MEASURES TO BE TAKEN BY PRIVATE OWNERS TO INSURE A TIMBER SUPPLY FOR THE FUTURE.

It is, of course, apparent that the perpetuation of our timber supply depends upon the proper handling of government, state, and private forest lands; not only that a second or future crop be secured, but that much greater ones will result. This has been done abroad and can be done in this country. Each holder must manage his lands in a rational and conservative manner. The Government must not only manage its own lands wisely, but must aid States and private owners by information and assistance; the State must aid the individual or company by wise and just fire and tax laws, so that lands will not be stripped of their timber to revert to the State for nonpayment of taxes; the private holder must so cut his land that a second crop and a better one will result.

One of the chief reasons why private owners have not more generally practiced forestry is that they have had a very vague idea of what forestry means, and of the benefits that might be expected to result from its practice; and many have still a very vague idea of what should be done to insure future crops. As has been pointed out, the method of forest management must, in every case, depend on the section of the country and even on the specific tract. In fact, it very often happens that conditions are so different over a comparatively small area that several silvicultural systems must be followed.

Yet there are certain peculiarities common to any forest region. Thus, in certain portions of the yellow-pine belt of the South (loblolly and shortleaf lands), if fires are kept out and from two to four seed-bearing trees are left on each acre, a fine stand of young trees will be secured. In the pine region of the Great Lakes, the brush, composed of poplar and wild cherry, comes in so soon after cutting that it takes several years for white pine to regain a foothold. In the southern Appalachians it often happens that the tree most desired in the reproduction is the most valuable one for lumber, and is so scattered that the logger feels he must take every one of that species and leave the less desirable kinds to seed the ground. The same thing is true in the Douglas fir forests of Washington and Oregon, and in the spruce and fir forests of Maine. In each of these cases inferior trees grow with the superior ones, and when the latter are cut the inferior are left in possession of the ground. In some cases it is necessary to destroy the inferior species, while in others careful cutting will result in a renewal of the desired kind. There is in every case a cheap and effective way of working out the problem.

A timber-land owner with property worth $50,000 should not hesitate to spend from $2,000 to $3,000 for the services of a forester in order to find out the best way in which to manage his lands. The owner of a small tract can get aid from the Federal Government and from the States either free or at a very slight cost.

WHAT THE STATES SHOULD DO TO PERPETUATE THE FORESTS.

By Filibert Roth,
University of Michigan.

SUMMARY.

Aside from their economic functions forests have certain peculiarities as property which necessitates the passing of special laws for their protection. The chief of these peculiarities are:

1. *The time element.*—It may take one hundred years to produce a finished crop. Hence continuity of purpose and treatment are necessary.
2. The growth of each successive year on any one acre is held for years and remains as visible and taxable property. Hence there arises the common and wholly unjust practice of repeated taxation.
3. Timber tracts should be large in order to permit the most efficient management and utilization.
4. Forest land is usually cheap land. It is the tree growth which makes up the large part of the property.
5. Forests are most extensive where agriculture least succeeds, and where, therefore, there is a sparse population.

The state action which is essential for the perpetuation of our forest resources should follow along the main lines which experience has elsewhere shown to be essential. They are:

1. *Forest legislation.*—Proper forest protection is indispensable if private owners are to put timber land upon a permanently productive basis. The States must enact laws which result in effectually preventing forest fires. Much of the expense for fire protection may justly be placed upon the forest owners, but the State must safeguard forest property and provide the machinery for enforcing laws for the prevention and fighting of fires. The methods of taxing forest lands should be so modified as to encourage holding them until the crop is fit to cut or another crop is produced.
2. *State forests.*—These should cover all the rougher and poorer lands in every timber State where sufficient national forests to protect watersheds and maintain a timber supply do not exist. There is especial need that in many cases the States should buy up large areas of cut-over land within their borders and maintain them as forest reserves. New York, Pennsylvania, and Wisconsin have already adopted this principle on a considerable scale, and other States are beginning to apply it.

In discussing the subject of forestry as the care of the woods of our country, the questions constantly come up—

"Why do you ask for legislation and other state action?"

"What is there about the business of forestry that justifies such action or makes such action desirable or necessary?"

"Is forestry of such great importance to the people at large?" or

"Is it such a peculiar business that it can not get on without state action?"

These questions are pertinent; they must be answered before suggestions for state action can be considered. Briefly it can be said that forestry asks for no bonus or special favor; it is an honest, paying business, and merely asks for the "square deal." Forestry is of vast importance to the welfare of our people; it ranks fairly second to agriculture in most of our timber and mountain States.

Some of the laws of the States are positively inimical to forestry; they make forestry as a business impossible, chiefly through unjust taxation and an utter lack of protection of rural property. These laws were mostly framed when the very word forestry was almost unknown in the country, and, therefore, without any bad intention, they left out the consideration of forestry as an important industry.

The following somewhat categorical statement will help to make this clear:

I. REASONS FOR STATE ACTION.

(a) THE IMPORTANCE OF FORESTRY TO THE PEOPLE.

1. *The timber supply.*—The rapid development of the iron and steel industry and the substitution of metal, stone, brick, tile, and cement for wood somewhat misled most people into the belief that the importance of timber in the household of the nation was on the decline; that we would soon be able to do without wood, and hence without forests. The fallacy of this notion is fully illustrated in another chapter of this report. We use more wood than ever, and we now realize as never before that wood is fundamentally necessary to most of our industries to-day, and that with the depletion of coal and iron (both in the reasonable future) wood, again, must form one of the principal bases of man's comfort, of his very existence. For timber may be grown always, providing we do not destroy and lay waste the earth beyond the point of recovery, but coal and metals are mined and sooner or later give out.

As stated elsewhere, in Europe, where the per capita consumption of wood is only about one-sixth what it is with us, every State that has less than 35 per cent of its land in forest is an importer of wood and timber.

The price of timber for more than one hundred years has been more uniform and has increased more regularly than that of any other raw material. This is true not only of our country but is true of all parts of the civilized world.

Wood is used so universally in every household that excessive prices, like excessive prices in bread, react at once and seriously on the welfare of all the people.

2. *The use of land.*—In the Old World, as well as with us, millions of acres of land that were once cleared of forest and tilled have been abandoned by the farmer. In the New England States alone the census of 1900 found that between 1880 and 1900 fully 40 per cent of all tilled land had been abandoned. The tendency of modern agri-

culture is to farm intensively all good lands and lands favorably situated (about cities) and to withdraw from the poorer regions. The importance of this phase of the problem varies with different States. It means little to Iowa, where 95 per cent of all land is good agricultural land, but it means much to the Lake States, the Appalachian and New England districts, and the South, and means still more to the States of the great mountain region of the West, where many millions of acres are at too high altitude to warrant any farming, even if it were otherwise possible. All of these lands can and should be occupied by the forest, and by the use of these vast areas the forest will make a crop which will mean hundreds of millions of dollars to the people of these several States.

3. *Forest and water supply.*—The irrigating States of the West depend to a large degree on the forest to secure to them the water supply on which their agriculture is based. But even the farmer of the Central States experiences a continental climate where, every year, hot, dry spells, accompanied by severe, drying west winds, injure or destroy part of the crops. A well-distributed forest cover is the only remedy (aside from tillage of the soil) which can ameliorate these conditions. It is demonstrated by experiment that this action is of value, and there is to-day no doubt that the presence of such a forest cover frequently decides between a modest crop and an utter failure. It is here not a matter of heavy precipitation or other extraordinary action; it is merely the difference between much dry wind blowing freely over the land and the same dry wind checked locally from field to field by the scattered wood lots and the larger bodies of timber.

The influence of forest cover on the flow of streams and the general distribution of the water supply of any region is to-day universally conceded. But such an influence is of enormous value to the people of most of our States. Nor is this all; this value is on the increase; the development of water power and water transportation, going on all over the civilized world, is making this action of the forest one of first magnitude.

4. *Forest and erosion.*—The question of erosion is of such fundamental importance to every people and in every State that it well deserves special consideration. The farmer of Iowa or Mississippi may care nothing for the forest to supply him with timber, he may be indifferent as regards his crop or water supply, but he can not afford to see his land washed gradually but steadily into the sea.

The injury due to the gullying and washing of our lands is still too little appreciated. Even in the Lake States, where we have always been told about the low gradients of our river systems and the consequent safety against erosion, we lose thousands of acres of fertile land every year, as well as the choice top soil of many thousands more. This loss is enormous; it is permanent; it makes for waste land and for desert. The forest cover, properly distributed, is the only practical means of preventing it. With the experience before us of the Mediterranean countries and the sad stories of the Chinese Empire, showing two thousand years of steady deterioration of millions of acres of land, the gradual driving from the land of millions of people, and the final dissolution of once powerful nations, surely we, the enlightened people of the twentieth century, have little excuse for our indifference.

5. *Forest and æsthetics.*—Man loves the woods. The throng of the city on a summer day is not about the piles of hewn stone and brick or brownstone fronts; it is out to the woods to enjoy the shade and beauty of the trees. This is not new; it is not due to school influences or any other artificial means; it is instinctive, rooted in the very nature of man. The traveler who finds southern Michigan to-day a "pretty country," does not mention the red barns nor the "bill-posted" back yards which the towns offer to the passing train; it is the woods, and the woods chiefly, which make this southern Michigan, like many other parts of the Union, attractive to him. The æsthetic value of the wood lots of Michigan is worth many millions of dollars, which are capable of being lost by the removal of these woods.

6. *Forest and ethics.*—Generally we preach one code of ethics for the ordinary man, another for the "extraordinary" man, either on top or at the bottom of society, and usually no code at all for the State or Commonwealth. We are getting over this Machiavellian habit, and surely, if it is proper for the ordinary man to leave to his children a decent heritage, to leave the farm as good as he found it, it is equally the concern of the State and of us individually, the people of to-day who make up this State, to leave it in as hospitable and beautiful a condition as we found it, and to avoid, at least, serious devastation. The devastation of the forest cover is one of the most conspicuous of all. The logging of the mature white pine in Michigan was good, sound business; the conversion of millions of acres of forest into blackened stump waste was a serious and unwarranted mistake; the continued burning and devastation of these same lands by a prosperous people is nothing less than a crime.

(*b*) PECULIARITIES OF THE FOREST.

In legislation or state action the peculiarities of a business necessarily require special consideration. Our attempts at railway legislation illustrate this perfectly. The forest—and with it the care of the forest, or forestry—has its peculiarities, and some of these are so very conspicuous and important that Dr. B. E. Fernow, in his excellent book, The Economies of Forestry, emphatically speaks of the forest as a property "sui generis," or peculiar enough to go into a class by itself. This same idea has served as basis of forest regulation and legislation in Europe for centuries past.

The following are probably the most important and most self-evident of these peculiarities:

1. *The time element in forestry.*—It takes many years to produce a finished crop. Timber in Germany to-day is cut at an average age of about ninety years.

2. The growth of each successive year on any one acre, i. e., the part which corresponds to the farmer's crop of the same year, is held for years, and thus remains on the land as visible and taxable property. To illustrate: Suppose a farmer plants 20 acres with corn and 20 acres with pine in 1908. In October, 1908, the corn crop is ripe, is harvested, and is sold, fed, or eaten probably before April, 1909. This crop is not taxed at all. The field is assessed as land and as land only. In October, 1908, the little forest trees, too, have

C

ripened a crop, one of wood. It is a small crop, but it is a crop, and it stays on the land. By the year 1940 the cornfield has been planted 32 times and has furnished 32 crops, and the crop has never been assessed or taxed. By the year 1940 the pine trees have also made 32 crops, and all 32 crops are still on this plantation of pine trees. But now the assessor, according to our law, must assess this plantation at cash value, or as much as a box maker or wood dealer could and would give for the pine. In 1950 the pines are still there and each year's growth or crop is added and the assessment raised accordingly. If the two fields are alike in quality, the cornfield continues to be assessed at, say, $50 per acre, but the pine field is assessed $50 for land and $50 for the pine, or $100 in all. This continues up to the time when the pine is cut or harvested, say at eighty years. When that crop of pine is 75 years old the farmer is really assessed on the land and also on 75 successive crops, i. e., the growth of seventy-five successive years, on all of which he has paid taxes before and on a large part of which he has been taxed repeatedly. But this method of taxation is prescribed by law in practically all States of the Union.

3. A large part of the timber crop may actually be used (cut or sold) long before the forester declares the crop ripe, i. e., long before it is the best business to cut it.

As pointed out above, the pine could be cut for wood at twenty, for pulp at thirty, for box material at forty years, and yet it is really best for the owner and indirectly best for the people and the State that it remain and grow into saw timber, or to an age of 100 years.

4. The size of the woods has much to do with the value of a forest property, and European people have found long ago that it is bad policy to allow timber lands to be cut into too small areas or parcels. The reasons for this are many. The woods, the trees, do better in the interior of a 100-acre lot than a small 5 or 10 acre lot where wind and sun can dry out the ground. In case of fire or storm the man who owns only 10 acres of woods may lose everything, but the man who owns five tracts of 600 acres each is not likely to lose more than a small part of what he owns. The man who has only one or two logs of oak to sell in our town has to give them away or even hire a man to take them away or cut them into firewood; the man who has 200 oak logs to sell can readily find a buyer at $15 per thousand feet b. m. The experience of Europe, and of our own country as well, clearly shows that as soon as a forest is cut into small tracts it is apt to be cleared or devastated.

5. The long period between sowing and reaping necessitates in forestry that there should be continuity of purpose and action. For this reason the forests belonging to States, cities, and towns, or all large woods under direct state control, have fared well, while most private forests, especially the smaller holdings, fare poorly. This fact led, centuries ago, to more or less state interference and control of private forests, a control which even at the present day is rather on the increase than decrease among European people. The common use of the wood lot reminds us of the cases so often met with in this country. The father takes care of the wood lot, saves the large oak, ash, and other valuable trees, uses the inferior material, and in this way stores up values fully as good as bank deposits. The son, who has early learned "better" (?) living, has a poor crop, he needs

money, and cuts the small forest. Then for a while it does not bring in any income, he tires of holding and waiting, and clears it irrespective of the future value of the farm. This case is thoroughly human, it will always be so, and only the strong hand of law can compel the son to regard the wood lot as property of a peculiar kind, from which he may never use more than the growth or real crop, and which, owing to its relation to the rest of the people, he may not clear or devastate without special permit.

6. The land used in forestry is usually cheap land, and it is the tree growth which makes up the larger part of the value. Thus the state forests of Württemberg have for years brought a net revenue of over $4.50 per acre per year. Capitalizing at 3 per cent, they are worth $150 per acre, but the land itself would be dear at $30 per acre and would not be worth $10 for agricultural purposes. Probably half of all the forest land of all central Europe could not be farmed permanently, but would become waste land in time if allowed to be cleared.

7. The capital used in forestry is large, and large holdings are desirable. The amount of labor is small. Thus $2 per acre a year is a good allowance for expenses even in Germany, while in farming, even with us, $10 per acre is but fair.

8. The net returns in forestry are rather large and are safe, and, considering the quality of the land for other purposes, these returns are often astonishing. In our country this is evidenced by the large crops or stands of timber in some of our mountainous districts and on the large expanses of sand, both North and South.

In the Old World much more exact data are available. Thus the state forests of Baden, Württemberg, and Saxony, aggregating over a million acres, have for years exceeded $4 per acre a year of net income. When it is remembered that good farm lands over a large part of the lower peninsula of Michigan are unable to produce this as cash rental, the showing surely is extraordinary.

9. The forest, unlike most agricultural crops, improves the soil and prevents its washing. The forest can use poor lands and frosty districts or situations which are otherwise valueless. This with its power to regulate stream flow and water distribution generally has forced the states of Europe into a recognition of the conception of the "protection forest," the forest which is valuable chiefly because it protects the land and prevents waste and desert and general injury to the people or state. This conception is general and fixed, and its use is extended more and more throughout Europe. Interesting is the fact that it was this conception of the protective value of the forest which decided the Congress of the United States to pass the first really important measure in favor of forestry in the New World, namely, the establishment of the national forests.

10. The forest is usually most extensive where agriculture least succeeds, and where, therefore, there is the sparsest population. But the forest can not be locked up, it can not be inspected in all its parts at a glance; on the contrary, the forest offers seclusion and a hiding place for the evildoer, and it is therefore one of the forms of property which needs specially rigid legislation and enforcement of law for its protection. This fact was recognized early in the development and settlement of central Europe. As early as the year 1200

the local laws governing the conduct of people in the use of the forest dealt with this fact, and trespass in timber, changing of boundaries, and setting fires in the forest, etc., were all treated as special offenses. And universally it was believed necessary to provide regular guards to protect the forest, a fact entirely overlooked and neglected in our States.

II. WHAT THE STATES HAVE DONE AND ARE DOING.

ABROAD.

In central Europe, where forestry really had its beginning, the states, as represented by the ruling princes or monarchs, began as early as the year 1000 to give special consideration to the forests. The compilations of local laws, known as the "Sachsenspiegel" (1215) and the "Schwabenspiegel" (1273), recognized the importance as well as the peculiarities of forest property. As early as 1304 Emperor Albrecht ordered the reforestation of devastated areas in the Palatinate. In France the laws of 1346 organized a regular state forest service, though more or less of this organization had existed for over a century. As the states of central Europe gradually took on more definite form, the numerous local laws, orders of the nobility and the clergy, the regulations of town and village, were replaced by regular state laws, or laws having effect alike in all parts of a given state. Thus, for the little state of Württemberg the law of 1515, revised in 1641, remained state law until 1879, a period of over three and one-half centuries, and is practically in force to-day. In Bavaria the law of 1568, revised 1616, remained in force until 1852, and forms the body of the existing forest law of that state. Similarly in Baden the laws of 1614, which replaced several special laws dating back as far as 1448, remain in effect to-day. In Hesse the local laws, promulgated as early as 1338, by free cities, cloisters, and certain of the nobility, and having effect only on the territories belonging to these several powers, were replaced by the laws of 1520, 1605, and 1628.

In Saxony the laws or "Forstordnungen" of 1560, 1585, and 1598 serve the same purpose and affect the forests of the prince, the nobility, and all subjects. In France the law of 1669, as part of a general system of progressive legislation, compelled all owners of forests to obey certain regulations, believed by the great Colbert to be for the welfare and power of the state. These laws were not mere decorations or a screen for game preservation; they were plain business and proposed to avoid the devastation of the forest, to prevent scarcity of raw material for shop, mine, and marine, and to keep the useless lands covered with a useful growth. They were too severe, and were abolished by the revolution; the state forests were sold and destroyed, the private forests devastated. In 1801 a new law was put in force and a forest service organized. In 1827 the old law of 1669, considerably modified, to be sure, was reestablished, and since that time France, though a republic for thirty-seven years, has "tightened" in the matter of forest legislation.

Even Russia with its enormous forest wealth, its vast stretches of unexplored and unexploited woods, has seen fit ever since 1645 to pass special laws with regard to forest property and its use and protection.

These laws of the different European States were a matter of development; they represented even in their first form the experience of centuries, and accordingly they have stood the test of time and prove of value to-day.

Generally these laws cover the following principal points:

1. *The ownership, purchase, sale, and management of forest property by the State itself.*—Thus every State of the German Empire owns and operates forests. The same is true of France, Austria, Hungary, Scandinavia, Russia, and other States. A notable exception is Great Britain, which owns hardly any state forests at home, but has one of the most extensive state forest systems in India and other colonies.

In Germany the States own 33 per cent of all forests, in Austria 7 per cent, in Hungary 15 per cent, in France 12 per cent, in Russia 66 per cent, in Sweden 33 per cent, and so on. These state forests are in numerous scattered parcels, and are cared for by a regular service, an organization made up of technically trained foresters assisted by a corps of protective men or guards. The expenses and income are handled by the treasury department of the State, the management is for profit, and the net income reduces by just that much the tax burden of the State. In spite of all attacks on the policy of the state forests, which were especially severe during and after the French Revolution, this policy is thoroughly established in every civilized State of Europe; it is fully appreciated and approved by all people, and the state forests are steadily increasing in almost every State. The indications are that the future of all large holdings in Europe lies in their ownership by the State itself or by corporation, city, or village under direct state control.

2. *The supervision or control of forest property by the State.*—This varies with different States; includes generally all forests belonging to cities, villages, and other public bodies, but in a number of States it is extended also to all private forests or at least to private forests under certain conditions. Usually this supervision tries to secure to the forest a businesslike care and prevent every form of misuse; and in most cases it prescribes the employment of technically trained men, the approval by state authority of the plans under which the forests are managed, and state inspection.

3. *Laws forbidding the further clearing of land or removal of the forest.*—This is really the oldest form of state action which attempts to conserve the forest cover. In some form or other laws of this kind date back as far as the year 1200, a time when the want of accessible wood material made itself felt at least locally for the first time among Teutonic peoples. These laws, which were practically general at one time, have been much modified; in some States, like Saxony and Prussia, they have been practically abolished; in others, like France, restricted to forests, taking on more or less of the character of protective forests. Generally these laws apply to all forests and provide that the owner of a forest can not clear without securing a permit from the state authorities.

4. *Laws forbidding devastation or misuse of the forest.*—These laws also are very old, were almost universal two centuries ago,

are quite general at present, and like the preceding they apply to all forest properties. These laws call in the police function of the State only when there is evident misuse, but in this case give ample power to the authorities to interfere for the safety of the property; they have been much modified and in some States have been abolished entirely, but on the whole seem still firmly fixed with a tendency to extension through a more liberal interpretation of the idea of the protection forest. To illustrate their application: A private owner has 100 acres of woods in Baden. This forest is not really under state supervision like that of a village; he can make his own plan, hire a forester or not; he does not account to the State for the material he cuts, and is not subject to the state forest inspection. His forest is free, it is his. But he can not clear an acre without permission from state authorities, and if a state forester or rural police discovers that he is overcutting the woods seriously, to the extent of timber devastation (something like a modern Michigan logging job), the police reports the case to the authorities, an investigation is made, a hearing is had, and if the owner can not make a good case, he is warned, his cutting is stopped, he is ordered to reforest, and in extreme cases the forest may be placed for a period of years in the care of the local state forester, the State paying the owner such sums or giving him such materials as are taken from the property, and deducting the expenses which are involved in the care of the woods.

5. *The purchase and reforestation of waste lands and devastated mountain lands.*—This form of state action carried out, especially in France, the German States, Austria, and Switzerland, recognizes: The necessity of state action with regard to such lands; the necessity of forestry in the reclamation of such lands, and the inability of the private individual, the village, and even the county to do this work.

Centuries of experience; the gradual deterioration of millions of acres of land into wastes, and the accompanying evils of poverty, crime, and general lawlessness; the disturbance of stream flow, and flood, and drought—all these have taught the people and the states of Europe the necessity of this line of action. And to-day states like France, and Prussia, and the other German States, and even little Switzerland, have a regular appropriation for the purchase of such areas and for their reforestation. This work has become one of such magnitude and importance that it has resulted in the development of a definite state policy, in broad-gaged, farsighted legislation, and in the expenditure of enormous sums of money. The state usually appears as a buyer; it is represented at the auction sales of property; it buys in the land that is of little value and that is in danger of devastation. The states of Europe do exactly the opposite of what we do in most of our States, where the poor tax lands, etc., are crowded on the market at any price and to no purpose. In certain cases, as in the mountains of France and Switzerland, the state exercises its right of eminent domain and takes the lands on the principle of the greatest good to the greatest number.

6. *Adaptation of the tax laws to the nature and needs of forestry as a business.*—Though the methods of taxation of forest property are by no means uniform or alike in all States, yet they are everywhere so adjusted that forestry as a business is possible and they

do not form an inducement to clear away the forest. Like other forest laws, they are a matter of centuries of trial and adaptation. Up to recent times forests were generally taxed on the ordinary plan of a "ground rent," or soil tax, just as the farms are taxed in our States. This form of taxation is ancient; it taxes the land only and is therefore based on what the land can produce or what it would bring if sold. In recent years this form has given way extensively to the income tax, which is based on the net income which is derived from a piece of property, and the tendency throughout Europe is toward this form of forest taxation as the only scientific and just form.

7. *The protection of the forests by special laws and by a rigid enforcement of law.*—Not only is the forest property dealt with as a property deserving the attention of Government, but all its peculiarities—the extent of the areas, the difficulty of seeing or finding the damage, the greater difficulty of catching the evildoer in the act, the serious danger of fire in the forest—are fully recognized in the protective laws of practically every state of Europe.

But what is far more important, the state action does not stop here. It is not content, as it is with us, merely to pass laws for the protection of the forest, but provides for the enforcement of the law, and it does this unstintedly and at all times and in every nook and corner of the state. There is no confusion of authority, no shifting of responsibility; there is no game warden shifting responsibility on a firewarden, and the latter claiming lack of authority; there is no $50 expense limit for a whole township, as is the case in Michigan. On the contrary, when a fire breaks out in a French or German forest, the citizens are called out, the police and foresters direct the work, and the fire is fought till extinguished. It is treated as a common enemy, and fought by the people regardless of effort, until checked. The people are not paid $2 per day and thus tempted to have more fires, as is the case with us, but they are compelled by law to help and to work. Thus the village, the town, the county, and state all hold themselves strictly responsible for the protection of forest as of other property, and the taxpayer in a German state or in France knows what he is paying his taxes for.

8. *Laws regulating the traffic in timber.*—This is tariff legislation, is quite general, and is based on the same economic principles as is other similar action. The forests of the state, forestry, and also the manufacturing interests are usually considered.

9. *Special and clearly-defined treatment of timber or the products of the forest on all public systems of transportation.*—By this means the timber market, and with it the timber business or forestry, is on a simple, well-known, and stable basis as far as transportation is concerned, much to the benefit of forester and consumer.

10. Laws relating to "protective forests," i. e., declaring that large areas of woods have such critical influence on the welfare of the surrounding country by regulation of water supply, etc., that their management becomes a matter of public concern, and warrants police or state interference and supervision.

11. Last and least come a number of various state measures which may be grouped under the general head of "encouragement" laws. Strangs to say, this line of state action is rather new in Europe, and it varies from state to state in kind, extent, and consequent

value. In keeping with the modern belief in education, laws of this kind are becoming more numerous. In some cases the state provides, free of charge, lectures and advice to landowners, free plant material, etc.; in other cases it goes further and assists with money and men in projects of reforestation; and in several of the states encourages such reforestation by relieving the owner of paying taxes for ten to twenty years or usually for such a time as is necessary to make the trees of a plantation of some market value.

IN OUR COUNTRY.

When we remember that the per capita wood consumption in the United States is six times as great as that of other progressive people; that our national consumption has reached the enormous amount of about 40,000,000,000 feet of timber; that most of our forests are in private hands; that they are largely devastated, and that the remaining supplies are going just as fast as human ingenuity can convert them into marketable goods; and that there is no reliable, satisfactory, adequate source of supplies for this large people to draw upon in the future, the needs for state action must be apparent to everyone. And yet, compared with the magnitude and the seriousness of the problem, all of our state action appears as nothing.

State action in our country thus far has followed four somewhat distinct lines: (*a*) Protection of the forest against trespass; (*b*) protection of the forest against fire, as a special enterprise; (*c*) promotion of forestry by various means; (*d*) the establishment of state forests and forest organizations charged with the care of forests.

1. The laws against forest trespass form part of the general code of each State; they were carried from State to State and were originally borrowed from the Old World and modified to suit. In our older States these laws have been in force a long time; they are generally quite simple and direct, and usually prescribe rather severe penalties—one of the many reasons of their nonenforcement. Thus, for instance, in Michigan, according to section 11749, a case of willful or criminal trespass, though it consist merely of cutting $30 worth of timber, can be punished by five years in the penitentiary and a fine of $2,000.

These laws are not uniform; they differ in form and severity for different States, but in practically all States they are quite sufficient. But they are not enforced, and never have been in any State. The machinery for their enforcement is wanting. If the owner or his agent catches a man taking timber, he can prosecute through the proper office, bring the case into court, and if he can get the jury to convict, he can get the evildoer punished. It is a matter between owner and court and not one of police.

For a farm owner who occupies his 160 acres, this may be quite sufficient, but for the man who lives in Detroit and owns 25 different parcels of forest scattered over several counties of the Upper Peninsula, this machinery does not suffice, and in his case he must either provide his own police or leave the law unenforced. Neither town, county, nor State concerns itself about the matter, though all three share in the taxes which are paid by the forest owner.

This is one of the causes of the peculiar attitude of the local people toward the nonresident forest owner. Though, in truth, these resident people often make their living from the tax money of the nonresident, and though the latter contributes toward every rod of road and every schoolhouse built, and other improvement, yet he is treated as if he were a wrongdoer, is taxed unmercifully, and, in addition, a trespass on his land or forest is excused and it is almost impossible in many places to get conviction. This has led in most forest States to peculiar conditions.

Thus in Michigan and other States the State itself gets no protection from the local authorities. The system of government is entirely perverted, the sheriff and the town official may even share in trespass on state lands and the State is driven to adopt a makeshift police system in the form of state trespass agents, whose business it is to guard the interests of the State.

We have here literally one part of government of the State organizing against another, or at least to do the work of the other—the part properly established by constitution for this purpose and elected under this constitution by the people. But no one is obliged to do his duty. And here lies the weakness of all forest protection by the State of Michigan as elsewhere.

That this lack of protection against trespass has not helped to conserve forests is easy to see. The owners of forest lands have been involved in endless litigation. Where the situation has been very bad they cut the timber. In many cases timber stealing was hidden by setting fire to the slash and thus wiping out the telltale evidence of cutting.

Generally speaking, the trespass laws have helped; they have protected against large and continued trespass, but their general nonenforcement by the proper authorities themselves has done serious and lasting harm to forests and forestry.

2. Usually with the first code adopted by each State came laws, derived like the laws on forest trespass, dealing with the prevention of fires in forests and on prairies. Like the laws on trespass, these earlier efforts are simple, direct, and severe. Thus in Michigan, as early as 1846, the law provided a penalty for willfully burning the woods of another, amounting to as much as five years in state prison and a fine of $500. Quite early, and in some cases as parts of the first protective act, came provisions making the fighting of forest fires a special duty of the supervisor, the justice of peace, the highway commissioner, or some other official, giving these officials power to call out the citizens and making it obligatory, under severe penalty upon the citizen, to obey such summons and to help in the fight against fire. The responsibility of the local authorities was thus clearly recognized at an early date. But there was a penalty prescribed only for the citizen and not for the officer, and so the officer found it to his political interest never to call people out.

Thus these laws (even more than the laws of trespass) remained dead letters. The difficulty of catching the evildoer, together with the ease of finding excuses in having to clear land, burn brush, cook food on camp fires, etc.; then also the matter of accident, the pipe, cigar, match, and torch, all allowed in the forest at any time and season; the general permission of anyone to travel, camp, hunt, and fish on other people's lands; all these made it practically impossible for the owner or his agent to bring the matter into court and secure conviction. And even if conviction were obtainable, it would have been of little value, for it is prevention of fire and not merely conviction of the firebug that is wanted. And here again State, county, and town did nothing; and with this the sense of individual as well as corporate responsibility disappeared. No one raised a hand, and the evildoer, the lone, shiftless do-nothing, who maltreats his family and his animals under the guise of being a pioneer settler, and who is ever ready to see the woods burn, could fire it to his heart's content. He could vent his spleen, or spite the thrifty neighbor; he could right the wrongs which his vicious imagination made him believe that he had suffered at the hands of the lumber company, and he could tell of the "two men with guns" whom he saw, or the "city guys" who camped there, or invent any other of the multitude of cock-and-bull stories which are circulated regularly and given emphasis by the press and the townspeople who know precious little of the situation.

It was in this way that the hundreds of fires have been started every spring for the last forty years, and it is in this way that hundreds of fires spring up in dangerous dry summers like that of 1908 and rapidly eat up the forest cover over millions of acres of land.

After a number of really great calamities, like the fires of 1871, 1881, and 1894 in the Great Lakes region, where hundreds lost their lives and thousands were made homeless, and where the damage ran well up into the millions, the situation became positively intolerable. The people clamored for action, and the legislatures reluctantly enacted a series of laws, all of which were more or less modifications of the old fire-fighting laws already in existence, and collectively perhaps best termed "firewarden" laws. Like the trespass agents and game warden laws, they are a makeshift, a duplication, and interference in what should and could be the proper administrative body of the state government. The Michigan law, copied and modified after that of New York and Minnesota and again copied by Louisiana, etc., illustrates this phase of state action. The State had a good, simple, though somewhat incomplete, forest-fire law, with a provision which made it the duty of the supervisor, justice, and road commissioner to call out the people and fight forest fires. Beyond this the State never spent a cent in protecting its second greatest natural resource and its second industry.

After enormous losses and years of agitation, the legislature in 1903 made the state land commissioner a state forest commissioner (and this in spite of the fact that he already was a member of the state forestry commission), with power to appoint a state firewarden. This man, with a salary of $500 a year, had authority over the supervisors who were thus once more legislated into the firewarden job. The earlier law was repeated in its main features, but the people were to receive pay for fighting fires, and the sum total spent in any one town should not exceed $50 in any one year, so that if $49 should once be spent the people must be sent home because no more money was available. Of this law the state land commissioner himself, in a public meeting, declared that it was not worth the paper it was printed on.

In 1907 the power of the land commissioner was transferred to the state game warden, who was made fire and game warden, the idea being that this office, equipped as it was by law with deputies scattered over the State, was practically a police body and thus would do better work. But when the writer asked a deputy game warden, on September 11, 1908, if he had any instructions, the reply was negative. Though the whole country was on fire and though every supervisor was by law compelled to fight, it was deemed unnecessary even to issue instructions. Again, no officer is obliged to do his duty.

The utter uselessness of these firewarden laws is amply proved by the fires of 1906 and of 1908 in Michigan; by the fires in Wisconsin, Minnesota, and New York. Aside from the small educational value of the posters, it is doubtful if these laws ever prevented a fire or put one out. The pay provision in these laws is generally conceded to be a mere temptation to build enough fire to get the state money. The forest still remains without state protection against fire.

3. The encouragement laws, or laws for the promotion of forestry in the several States, have so far been chiefly along two lines: The creation of forest commissions and, of late, state foresters, to gather and distribute information, make propaganda for forestry, and act as advisers to the legislature or government of the State; and the encouragement to plant trees or maintain forests by offering a bonus, or by exemption of the plantations from taxation. These laws have commonly been hedged in with numerous useless conditions and are usually considered unconstitutional. They have, perhaps, had educational value, but otherwise they have been of practically no use. These laws have neither planted nor preserved.

4. State action creating state forests or parks, and providing an organization for their care, has been of great and lasting value, and may well be regarded as the only one of the several state efforts which has resulted in unqualified success. Here come first New York and Pennsylvania and Wisconsin; then the smaller attempts of Minnesota, Michigan, Connecticut, Massachusetts, New Jersey, Indiana, etc., all of which have been of value. These state forests speak for themselves. They are an object lesson, and form the nucleus of what some day must be the principal center of state activity with regard to forests.

III. EXISTING OBSTACLES TO FORESTRY, WHICH THE STATE ACTION ALONE CAN REMOVE.

As more or less indicated in the preceding, there exist to-day in every State of the Union certain great obstacles to forestry as a business, and some of these threaten seriously even our present and rapidly vanishing timber supplies. These obstacles offer no extraordinary difficulties; they can be and will be overcome as soon as the legislatures of our States catch the "forestry spirit," which is now so unmistakably spreading among our people. Unfortunately, the legislatures have been reluctant in this matter; they have treated it as of the "reform sort of thing," to be looked upon suspiciously and to be put off for future and better consideration and understanding.

It is a remarkable fact in this matter of forestry, which is a purely economic matter and to the legislator means only the adjustment of law to the needs of a useful and necessary branch of agriculture, that where 90 per cent of our people are agreed that the proper measures should no longer be delayed, we still find the legislatures hanging back. In fact, there are few legislatures of the last five years where even 2 per cent of the legislators displayed any interest in the matter, and still fewer where even a single man could be found who was willing to put his shoulder to the wheel to accomplish what 90 per cent of the people would be glad to support.

Nor is the matter so technical. There are various ways in which the obstacles may be removed, and almost any effort can be modified and improved as time goes on. Good will and good sense are the only requisites.

The obstacles to forestry which state action alone can remove may be grouped under the following four heads: Taxation to the point of confiscation; lack of protection of forest property; personal liberty to the point of license; mistaken policy regarding state lands and the holding of lands by all public corporations, counties, towns, and cities.

1. *Unfair taxation.*—Every owner of forest land in almost every State is agreed that unjust taxation has led to premature and hasty forest clearing. Here again the conditions existing in Michigan, which apply to most of the States, will help to illustrate. In Michigan the distinction is made between the assessment and the rate of taxation, for it is the latter especially which has operated injuriously.

The assessment, according to present law, is at "full cash value" of the property. It assesses the growing crop as well as the land. How this would affect a case of reforestation has already been pointed out. It makes the tree farmer distinct from the corn farmer; it assesses only the land for the latter and the land and crop for the former, besides piling up the assessment all through the life of the trees. This method of assessment, then, is absolutely prohibitive to any effort at reforestation.

In the case of the man who owns and holds a forest already in existence the case is less unfair. He can cut and sell timber, but even here it is in danger of becoming unfair, and it usually does become so in practice, since this assessment in nowise takes into consideration what the property is making for the owner. In the case where the forest is bought merely to lumber it—that is, when only the stumpage is sold—this assessment is fair and correct in principle.

The unfair practices of excessive assessment of the forest and excessive taxation of the nonresident owner, together with the lack of satisfactory safeguards against these, need not here be considered, though these, too, have worked a great deal of harm to the forest.

The total tax rate is made up of state, county, and local (town, highway, school, etc.) tax rates. The first two are usually not high in any State. Thus for 1905 we have for Michigan: state tax, $2.46 per $1,000 of property; county tax, $2.40 per $1,000 of property; township, school, and highway, $10 per $1,000 of property; total average rate for the State, $14.86 per $1,000.

The town, highway, and school taxes (the local taxes) are levied by the local people. The few residents of one of the thinly settled towns levy these taxes, and there is no law to set a limit or maximum, and they build roads and bridges, schoolhouses, etc., whether needed and justified or not. They can make, and often have made, a large part of their living by doing the jobs which consume the local tax. It is argued: "Yes; but they tax themselves as high as anyone." True, but their own little properties represent but a small part of the total property of the town. It is the nonresident who commonly pays 95 per cent of all txaes levied; and it is by working (?) out this 95 per cent that they make their living and the "representative" man or local politician makes his money. What this leads to is well illustrated by the following:

In 1901 the average tax rate of one county in Michigan was over $63 per $1,000 of property; in five other counties it exceeded $40, while in 13 more it exceeded $30. And every one of these high-taxed counties was a timber county, a thinly settled district, where the nonresident, land-owning taxpayer was bled for all he would stand. In some instances the combination of assessment and rate led to the levying of a tax rate amounting to over $100 per $1,000—confiscation in ten years.

For this reason it has been one of the common questions in the timber owner's office, when deciding on where to cut next winter, "How do we fare in ——— Township as regards taxation?" If the answer is "Good," the cut is not made; if "Bad," the decision is, "Then we will locate a camp there." It is not asserted that if the tax rate had been low or reasonable and honest that the forests would not have been cut; what is asserted is this:

If the State and local people had treated the owners of timber honestly and had spent a reasonable part of the taxes in giving the protection which the owner had a right to expect under the Constitution, there would still be more than half of our pinery lands covered by forest. But this was not and is not the case. A certain forest owner in Michigan paid during the last twenty-five years over $600,000 in taxes, and it would be difficult to prove that a cent had ever been expended in the protection or real improvement of this property.

The result of this is also well illustrated by Michigan conditions. As early as 1875 over 9,000,000 acres of land, one-half of the north half of the State, was returned as delinquent or "in soak" for taxes. The owners could not afford to hold the lands, and as soon as the then marketable stuff was cut they let the land revert to the State.

2. *Lack of protection.*—This has been partly discussed above. There has never been any responsibility anywhere. The town, county, and State have acted as if the forest were not property in the ordinary sense. This was and still is especially true of protection against fire. The town officials in most States, as in Michigan, were supposed to act, but they were not compelled to, while the county officials never concerned themselves at all. Even of late years (since 1903) the case has been no better. Now and then a bit of fire fighting is done to keep the fires out of the settlement, but even then there is no head, no method, no responsibility, and in some cases it seems chiefly a matter of earning $2 per day. As stated before, the new law in Michigan has helped nothing, for the very head takes evidently no interest in the matter. Besides this utter lack of responsibility in the execution of law and the fighting and prevention of fires, there is an amount of personal liberty allowed which long ago degenerated into the worst form of license. Everyone, irrespective of character and previous record, is allowed to travel over these lands, to hunt, fish, pick berries, and camp where he

pleases. In this way the woods are overrun by persons unknown as to name and character to any of the local authorities, and have long been the hiding places of the irresponsible and even of the criminal.

During the dangerous dry seasons some of these people are constantly setting fires, but the large areas and the difficulty of locating fire and people make it practically impossible for the few town officers to apprehend the culprits. Again, everyone is allowed to fire in order to clear land; and though the danger of this practice has been long recognized, even in our old fire laws, nothing effective has ever been done to regulate it. Under the pretext of fighting fire, or of protecting property by backfires, thousands of acres are burned over every year. In no case does the law prescribe sufficient care. Even in the driest season, when the cut-over lands especially are far more dangerous than any ordinary saw mill or similar establishment, the pernicious cigar or pipe is in common use; matches are struck and thrown into the dry, inflammable brush; campfires are built without regard to safety; shooting is done without excuse or need; and all these things go on without interference of law.

If some evildoer is actually caught in the act, the right to arrest him is not granted except to sheriff and a few officials who never concern themselves about the matter, and the man is allowed to escape. And even in cases where the guilty party is located, the juries are reluctant to convict except on the clearest proof, and the general record of the person as a notorious firebug is usually disregarded. The result is that, in spite of the fact that there are hundreds of forest fires set every year in the State, the writer knows of not one single case where the culprit has been convicted and punished.

3. *Personal liberty.*—Aside from its abuse in connection with forest protection, personal liberty has been and is held so sacred that the owner of forest properties is universally allowed to do as he pleases. He can cut and slash, burn and devastate, without interference.

It was not until within this year that at last the courts have begun to recognize the right of the Commonwealth in the matter of forest property and the treatment of it. That the misuse of any property is a wrong morally is conceded; that it is so legally is also conceded as soon as the misuse is truly serious or the property is of a peculiar character (railroads, etc.). That the unlimited, unrestricted misuse of forests by their owners was not only a mistake and poor business, but was a serious moral wrong and should have been made a legal wrong as well is just beginning to dawn upon our people.

4. *A mistaken policy toward the holding of land by the State, county, or other public body.*—Here we are concerned primarily with the matter of state lands. With the general craze to get all lands cleared and settled, and with the individualistic mercantile spirit dominating everywhere, it was but natural that the States of this Union should at all times have been eager to dispose of all their lands. That this policy resulted in much harm is now quite generally conceded, and in a few States a radical change of policy, or at least of the laws leading to such a change, has come into existence. Here again the conditions in Michigan serve well to illustrate the workings and results.

From the beginning the State sold, was eager to sell, fairly forced the sale of, all lands given to it by the Federal Government. It sold "cat in the bag" from the first and is selling in this same unprofitable manner to-day. The expense of a real examination was too great, and the faith in an examination by the usual political clique was too small, and so the lands went for what they would bring. For over thirty years thousands and hundreds of thousands of acres came back to the State for nonpayment of taxes (result of bad tax system). These lands cost the State millions of dollars in advertisements and clerk hire; they were again and again sold in the same fashion. To-day the State owns nearly a million acres of these lands, skinned and skinned again, several million acres come up annually "in soak" for taxes, and still the State spends money trying to get rid of them. During the past five years the State sold over 800,000 acres, received about $1.20 per acre for them, and now it is shown by special examinations that these lands had timber enough on them to pay the above sum twice over, and that thus the State gave away land and timber and young trees to the amount of millions of dollars. And what is even more pitiful, the lands thus sold are held by owners just long enough to cut off the timber—to burn them over; then they let them revert. Thus the land policy has robbed the State of millions of money, millions of acres of land, helped in further devastation of the country, and in many cases promoted a form of land speculation which is even worse than forest devastation.

Had the State kept its lands, sold them only on application and at a fair price, and separated all poor lands as forest reserves, it would have received more money, these reserves would now be producing an income instead of causing expense, and the State would be in a fair way to supply itself again with all forms of timber instead of having to import as it now does.

This general policy of "getting the lands on the tax roll" permeates all of our States. The timber counties of Michigan, of Wisconsin, and of other States could have reserved county forests and thus freed themselves from all county and state taxes by holding income-producing properties, and many of our towns could have done the same.

IV. WHAT THE STATES CAN AND SHOULD DO.

From what has been said it is clear that state action is necessary; that the lines of action be few and simple; and that such action should take very much the same form which forest legislation has taken in the older nations.

Categorically, state action should provide for: (1) A rational state land policy; (2) the establishment of state forests; (3) forest protection; (4) rational and fair forest taxation; (5) enforced right treatment of forest properties; (6) continuation of education in forestry and the encouragement of forestry among the people.

1. The State should cease to sell lands and become a purchaser of lands. It is clear that this measure must vary with the State; that it means not the same for Indiana as for Wisconsin; and that in the case of such a State as Iowa it may be dispensed with altogether.

But fundamentally it is good policy for the State to own land, and not only poor land, but good land as well, and especially for it to own all lands which do not promise a truly prosperous condition of settlement. This policy will be fought here, as it was fought abroad, and as it is now being fought locally in our States, by the land speculator, who revels in cheap lands—the natural goods of the land swindler. It will be fought also by the small local business man and the local politician, both of whom want, at any cost, settlement and people to live on, regardless of the ultimate harm to State and county.

As an illustration of the value of the States purchasing and owning lands and forests, the case of New York may serve. The Adirondacks lands were disposed of by the State at about 5 cents per acre; the State began buying back these lands in 1884; it has bought over a million acres, largely culled, at an average price of about $3.60 per acre, and to-day it has a holding worth at least $20 per acre, besides securing to its people one of the finest summering places and one of the beauty spots of the New World—in itself worth all that these lands have ever cost.

In purchasing lands by the States for purposes of forestry, it will be wisdom to buy good forests at good prices, as well as poor lands, and thus put the enterprise on a self-supporting basis as soon as possible.

2. Of the establishment of state forests hardly anything further need be said. If done honestly and liberally, so that the usual penny-wise, pound-foolish policy of our States does not spoil the enterprise, there is no reason why every forest State should not own and manage forests. If New Hampshire and the other New England States will only use their power of eminent domain, buy what mountain forests are needed to secure the beauty of that region, to control its waters and its industries, bond the States and secure the bonds by a mortgage on the woods, there should be no difficulty in making the forests pay the interest and, in a reasonable time, also the capital. If Michigan had kept its cut-over lands it would have had a good paying property to-day. If the Southern States will take over all their cheap cut-over lands, they will soon develop large properties which will be a blessing to future generations and prevent millions of acres of waste.

In discussing this matter much has been said in Michigan of having a certain part of every township in forests. It is a part of the scheme of leaving all forests in connection with farms, and thus making the farmer supply both wood and bread. But while it is highly desirable that the farm wood lot be preserved, that farm forestry be encouraged by every reasonable means, this plan will not suffice. There are whole counties in States like Wisconsin or Virginia that are practically all good land. In such counties the farmer will never be willing to devote more than from 3 to 5 per cent to forest, an amount entirely inadequate to supply even the farmer himself. On the other hand, there are in these same States entire counties where 85 or 90 per cent of the land is poor and not well suited to agriculture. Here the matter of forestry is foremost and becomes one of large holdings. If these holdings are in private hands it becomes either a matter of mischievous monopoly or else (what we now have) one of forest devastation and waste land, with constant conflict between the State trying to preserve and regulate and the owner trying to use up for his own present gain, regardless of waste. Under these conditions Europe has long since found out that it is only the State which will manage the forest well, and at the same time manage it for the good of the people.

State forests occupying all of the rougher and poorer lands should be the central figure of all state action in our country. What these forests can and should do financially has been mentioned and is discussed more fully elsewhere in this report.

3. The State should provide forest protection. In wrestling with this phase of state action the efforts have varied, but two distinct lines could always be recognized: The older measures, and those still most favored by the large majority of state legislatures, placed the burden on the town or locality where the property and the danger lie. More recent attempts, on the plea and assumption of inefficiency of the local government, have asked the State itself to undertake the protection by a properly organized state patrol. In the States where most legislation has been accomplished the discussion has resulted in a compromise, a state official, fire warden, or state forester, with one or more deputies forming the directive or administrative part, and a set of local fire wardens, either existing political officers, such as town supervisors, or else specially appointed fire wardens, forming the field service. In all cases these men are paid; the expense is usually divided between State and town. The wardens are clothed with power to call out the citizens, and the latter, and these only, are compelled to respond or be punished.

The older efforts, the placing of the burden entirely on the local people, evidently assumed that if the town gets nearly all of the taxes it should also do the bulk of the work. If the local people have to put out the fires, they will be diligent in preventing them, which is after all the main object to be accomplished.

Those arguing for state patrol maintain that the town is poor, and the burden too great for the few settlers, and that at any rate the town has proved entirely inefficient, so that if forests are to be protected the State must do it.

The use of the county authority has never entered the discussion, though in reality it may be assumed that the sheriff's office should furnish protection whenever the town authorities are unable to do so.

As stated before, in central Europe protection is furnished by the people of the locality fighting the fires, and patrol or prevention is secured through the foresters (on larger tracts), the local police, and the state police or gendarmes. But the chief feature here is that all must do their duty.

The writer himself has long favored a proper, paid state patrol, coupled with a form of special taxation which should place the financial burden on the owner of the lands to be protected. In providing state action the fact that prevention rather than fire fighting is the end desired should be kept in mind.

There are three distinct forms of state action that are to-day called for in forest protection:

(*a*) County and town should be held responsible for damages wherever it can be shown that a satisfactory, reasonable effort was not made by the town and county to protect the property against fires and incendiaries. When Allegheny County (Pittsburg) failed to make reasonable effort to protect the railway properties in 1877, the county was held responsible. This principle is just; without it government has no meaning. And this principle should be applied in case of forest fires. As stated above, our older laws, which simply demanded that the town fight the fires, were evidently based in part upon this principle.

If a certain county in Michigan had been held responsible for the fires of this year, the people would have prevented 75 per cent of all fires by prompt action; a number of irresponsibles would have been arrested and held until rain put an end to the danger; a number of others would have been brought into court and convicted; men would not have stood around with their guns on their shoulders merely inquiring whether the fire was coming their way instead of rendering the assistance which the law demands of them; nor would they protest against laws forbidding smoking in the woods, against the camper, hunter, and trespass during dangerous seasons, etc. This same responsibility would prevent the splitting of towns and counties. As it is, half our towns and counties were created to furnish jobs for local politicians who could no longer play boss of the larger town or county.

(*b*) Provide the machinery for the enforcement of law, the prevention and fighting of fires. Here the old original system as provided in Michigan would serve, provided it were made responsible and amplified. This could then well take on the following form: The citizens compelled to prevent and fight fires, as now, but ordinarily without pay from the State; the town officials compelled, on severe penalty, to do all in their power to prevent fires and to call out the citizens as soon as they learn of fires; the sheriff and his men to be fire wardens, compelled, on penalty, to arrest and bring to court any town official neglecting his duty as fire warden, and themselves compelled to call out men and act as fire wardens in the suppression of fires.

This system could and should be reinforced in every State by a body of state police to be distributed (say, one to each county) in all counties where 50 per cent or more of the area of the county is not occupied by farm settlers; these state policemen to act as regular police, patrol the district, enforce law in general, protect rural property, act as trespass agents for the state property, and also as game wardens if desired; to see that the county and town officials do their duty, and to have power to act as fire wardens, and in all greater emergencies to spend state funds for extra help used in such cases.

(*c*) Amplification of the forest-fire laws to regulate the following points: The right to go on other people's and state lands; the use of fire in clearing, in back firing, camp fires, etc., during certain seasons; smoking, the use of match and torch and firearm in and near forests during the dry parts of each year; the rights of men of bad record in and about forests; to make it prima facie evidence of guilt if a man is found near a forest fire where he has no business; to make it possible to prosecute officers and evildoers in a court sufficiently remote to insure impartial trial; to compel owners of woods to expend money in cleaning up their slash or guarding their forests in danger seasons; to give the right of arrest more liberally; to pay part or all of the fine to the informant. These provisions may seem harsh at present, but if enacted they would be taken as a matter of course within five years.

(*d*) The matter of forest taxation presents several difficulties. Usually the forest lands, and especially the large holdings of the lumbermen, were acquired not with a view to hold them and to convert them into regular forest properties, but merely as so much merchantable timber or material to be cut and sold as soon as possible or as fast as the market would take it. Since these formed the majority of cases, it was rather natural that the assessment should be made on the basis of what the material was worth or what the man paid for it. Then, again, the people argued: "This property was almost given away by the Government and has cost these men far less than it is worth, and as soon as they can they remove this wealth of timber and leave us the bare land." For these reasons it seemed even quite fair that the tax-gatherer should take rather a liberal slice, with the excuse that the money would serve to build roads and make other needed improvements.

But to-day the case is different. We are now eager to preserve these woods and to make the supply last as long as it will. And the owners of many of these forests are ready to-day to hold them and to handle them as regular forest properties. In addition, there comes the matter of reforestation of vast areas of land unfit for other uses, where there is no forest and where the case is entirely as on the farm; the trees will form a planted crop, due to the efforts of the owner. To complicate matters still more, we have certain intermediate cases where the owner is undecided, and asserts that he wants to hold part of his forest, but is not ready to say what part or for what period.

Generally it is conceded that the taxes should be so modified as to encourage both the holding of forest and forest planting, and these enterprises should not be discouraged. Various remedies have been suggested:

The special tax; merely a flat rate per acre of all forest land with the proviso that these taxes be used for specific purposes. This method is simple and feasible in every way.

Harvest tax; in this case a forest goes untaxed until the timber is cut, when a certain percentage of the sale value is paid as tax. This, more seemingly than in fact, has the disadvantage of leaving the local people without taxes for a number of years. In reality there would be a lot of timber cut in such a town every year, maybe by different owners, and thus there would be a steady though somewhat irregular revenue. This method would put a premium on holding forest and thus do some good; it is perfectly simple in execution, and therefore possible.

Combination harvest and land tax; here the land is taxed right along every year at its ordinary cash value, but the timber remains untaxed until cut, when a certain percentage of the stumpage value of the cut timber is paid as tax. This method has the advantage of furnishing a regular income, at least from the land.

Simple land tax to be applicable only to real forest properties and cases of reforestation; under this system the owner declares a certain area of forests or cut-over lands, wood lots, etc., to be forest property. He signs a contract with the State which gives the State a certain lien on the property; that it can dictate that the land may not be cleared and that the forest may not be devastated. This method is the simplest of all, applies to all woods alike, would work no hardship to anyone, would preserve the forest, furnish a regular tax income, and still enable the holding of woods and the reforestation of denuded lands.

In this case all timber not registered would continue to be treated in the ordinary way and might be taxed on the harvest-tax plan. It might be argued that this would leave too much property untaxed, etc. The fact is that the State of Michigan, for instance, could better afford to do without the tax from all its woods, making perhaps 2 to 3 per cent of all taxes, than continue to prevent by law so necessary an industry as forestry and the preservation of the forests now in existence.

An income tax or tax based on the net income of a forest property; here again a parcel or set of parcels of land would be declared forest property, the owner entering into an agreement with the State, and the assessment would be based on the net income (usually the average for, say, five years), at a certain percentage. This is thoroughly scientific and just and might be applied to any forest property, but in our conditions would often be difficult to use, since a regular yearly income from such a property is as yet the exception.

It is evident that this matter can be adjusted in various ways, and all that is really necessary is that there be a good will and that petty politics be left out of consideration.

All but the first of the above methods deal in reality only with the assessment and still leave the most mischievous matter, the tax rate, uncured. That this should be regulated, that every State should by law set a maximum at which any property may be taxed, should be evident. The only question is: What shall be the maximum? The average rate of taxation in Michigan is about from 1.5 to 1.7 per cent. For rural property in the well-farmed counties it is nearer 1.1 per cent, and certainly it should not be allowed to go higher in the poorly settled districts and on poor lands than in the good districts. The writer believes that $12 per $1,000 should be the maximum for all rural property. That the State has a right to do this, there can be little doubt. If not, it should have the right.

(*e*) The enforcement of right treatment of the forest by the owner is a matter of long standing abroad, and yet it has hardly been suggested in this country. The matter is quite plain, a simple law forbidding clearing without state permit and forbidding forest devastation under penalty will do the work. At first this will be quite crude, it will vary from place to place according to the notion of the officials, but in time it will work out to the good of the forest and of the people. If this form of action were properly extended, all forest taxation could at once be placed on a single land tax or on a net income basis.

(*f*) The laws encouraging and promoting forestry among the people may well be adopted more generally by all States. This line of action has met with favor from the first and no doubt will continue without much agitation. Work in school, the distribution of literature, free advice and free lectures by competent, trained men, the free distribution of plant material, the establishment of sample nurseries and plantations as object lessons throughout the State, the care of street and highway trees, will help to develop an understanding and love of the tree and the forest, and thus will repay a hundredfold in a better, more beautiful home for the generations yet to come.

PAST AND PRESENT PRICES OF FOREST PRODUCTS.

By H. S. Sackett,
United States Forest Service.

The industrial development of the country necessarily results in marked changes in many directions. One of the favorite topics of discussion of late has been the alleged increase in the cost of living resulting from the increased cost of commodities in common use. There has been a large increase in the prices of many things, but, on the other hand, there has been a decrease in others. The result in any given case depends upon the character of the commodity. If it be one, the raw material of which is increasing in amount with the development of the country or which is in such abundant supply that exhaustion is not feared, invention resulting in decreased cost of manufacture usually makes a reduction in the selling price. This has been the case with iron and steel, which are much lower in price to-day than fifty years ago. If, on the other hand, however, it be one, the raw material of which is decreasing in amount with the development of the country and the resources of which are limited, the price must continue to advance. Such has been the case with the forest products of this nation, the prices of which have increased greatly, especially during the past two decades. This increase, however, has not been gradual. On the contrary, the prices have fluctuated from time to time, depending on the prosperity or "panicky" condition of the country. On the whole, however, the general tendency has been upward. The reasons for this are manifold, but principally the increased price may be traced to an ever-increasing demand, coupled with the realization on the part of the American people that the raw material required for these products is not inexhaustible, a condition brought about largely by the wonderful growth and prosperity of the nation. So great has been the demand that even with the increased facilities for the manufacture and transportation of the finished product and the enormous substitution of iron, brick, concrete, etc., for wood, prices have steadily advanced and our per capita consumption of lumber has increased from 215 feet in 1850 to the enormous consumption of 480 feet in 1907.

The cost of labor and of supplies of every description has during the past decade increased greatly, yet there seems to be an impression that the lumber industry should absorb all these increased items of cost and charge no more for its product.

On the other hand, the increased facilities for the manufacture of the finished product have tended somewhat to equalize this increased cost of labor and supplies, but have only succeeded in a very small proportion and not nearly to the extent that is generally supposed. There is an opportunity in this connection to present some figures as to the actual increase in lumber prices and in value of stumpage, which enter so largely into the cost, that ought to be convincing to the most obtuse. To be sure, stumpage is only one item of many that enters into the cost of producing lumber, but it is one which can not be ignored and which is the real keynote to the situation.

From recent reports of the Forest Service and the Bureau of the Census the following table has been compiled:

Average value of stumpage and of lumber at the mill.

	Stumpage.		Per cent increase.	Lumber.		Per cent increase.
	1900.	1907.		1900.	1907.	
White pine	$3.66	$8.09	121.0	$12.66	$19.41	53
Ash	3.03	7.58	150.0	15.84	25.01	58
Basswood	1.50	6.79	352.6	12.84	20.03	51
Hickory	(a)	6.69	....	18.78	29.50	57
Oak	[b] 3.18	6.52	105.0	13.78	21.23	54
Spruce	2.26	[c] 5.49	142.8	11.27	17.26	53
Chestnut	2.71	4.97	83.0	13.37	17.04	27
Elm	3.30	4.94	49.6	11.47	18.45	61
Poplar	2.81	4.64	65.0	14.03	24.91	78
Cedar	1.32	4.63	250.0	10.91	19.14	75
Hemlock	2.56	[d] 4.51	76.0	9.98	15.53	56
Birch	(a)	4.40	....	12.50	17.37	39

Average, all kinds	....	....	....	11.08	16.58	49

[a] Not separately reported.
[b] White oak only.
[c] Eastern spruce only.
[d] Eastern hemlock only.
[e] Decrease.

First are given stumpage values of 1900 and 1907. Those in the latter year are the result of special inquiries made by the Forest Service, which secured more than 1,500 reports, widely scattered and obtained from authoritative sources. The lumber prices given are at the mills, and are derived from the total product for the respective years and the aggregate value.

The wood first upon the list is white pine. Its stumpage value increased 121 per cent, while the mill values increased but 53 per cent. More important, because of its larger product, is yellow pine. The increase in the stumpage value was 182 per cent and in lumber value only 65 per cent. Among the soft woods, the next most important item is Douglas fir; there the contrast is not so great, for while the stumpage value increased 87 per cent, the lumber value increased 63 per cent. Cypress shows a stumpage increase of 176 per cent and a lumber increase of only 66 per cent. Oak stumpage increased in value 105 per cent and oak lumber only 54 per cent. Cedar stumpage value increased 250 per cent and lumber but 75 per cent. It is unnecessary to go through the list, but it may be noted that among all soft woods the lowest increase in stumpage is only about equal to the highest increase in mill values.

The hard woods do not show such great discrepancies, but even there the contrast is marked in some cases, especially in oak and cottonwood. In some instances the lumber increase was greater than that of stumpage. The figures for maple, on first thought, might be questioned, as it is difficult to understand why there should have been any decrease in the value of stumpage as shown by the comparison. This may partly be explained, however, by the fact that maple is a wood which has a number of very strong competitors in all the uses to which it is put. This has to a large extent kept down its demand; and the building of railroads into hitherto inaccessible tracts of hard woods in the past few years has opened up a great many maple tracts and consequently thrown on the market large amounts of both lumber and stumpage, possibly even more than the demand warranted. However, the woods of largest production all show that the item of stumpage cost has increased in vastly greater ratio than the mill prices.

And why this increase in the cost of stumpage? During the past decade a most potent influence has been at work to cause this, viz, the awakening of the American people to the realization that their forest resources are not inexhaustible. The realization of an impending crisis has, during the past decade, made itself markedly felt in the lumber industry, and principally, of course, in the increase in the cost of stumpage. This is graphically shown in Table I. The increase advanced slowly for several decades but increased by leaps and bounds during the past few years. The only break noted in the continued rise in price since 1866 is from 1892 to 1896, when the decrease in price reflects the business depression which swept over the country at that time. Had not this occurred it is safe to presume that the advance would have been gradual from $7.00 in 1892 to $9.00 in 1898.

In case of wood we must not overlook that lumber prices do not really represent wood prices, for the price of a manufactured product like lumber, at places of consumption, includes the cost of manufacture, the cost of transportation, of brokerage, etc., and finally is influenced by the competition of manufacturers; changes in all of which conditions are reflected in the price. Thus it has happened that, owing to improvements in machinery, cheapening of transportation, change in methods of trade, and active competition, lumber prices have for quite long periods remained stationary, while stumpage prices, that is, wood prices pure and simple, have risen. For instance, the stumpage of white pine in Michigan rose during the twenty years from 1866 to 1887 from $1 per thousand feet, by constant steps, without a break, to between $4.50 and $6.50, while the white-pine lumber log run fluctuated during the whole period only between $11.50 at the beginning and $13 at the end, being never higher than $14 and, for five years of that period, sinking as low as $9 and $10.[a]

From this example alone we see that lumber prices do not move proportionately to wood prices and can not, by themselves, be used for the discussion of the latter. With regard to the variation of quality, we must keep in mind that wood is a material which serves two very different classes of purposes; namely, that in which the

---

[a] Report of Saginaw Board of Trade.

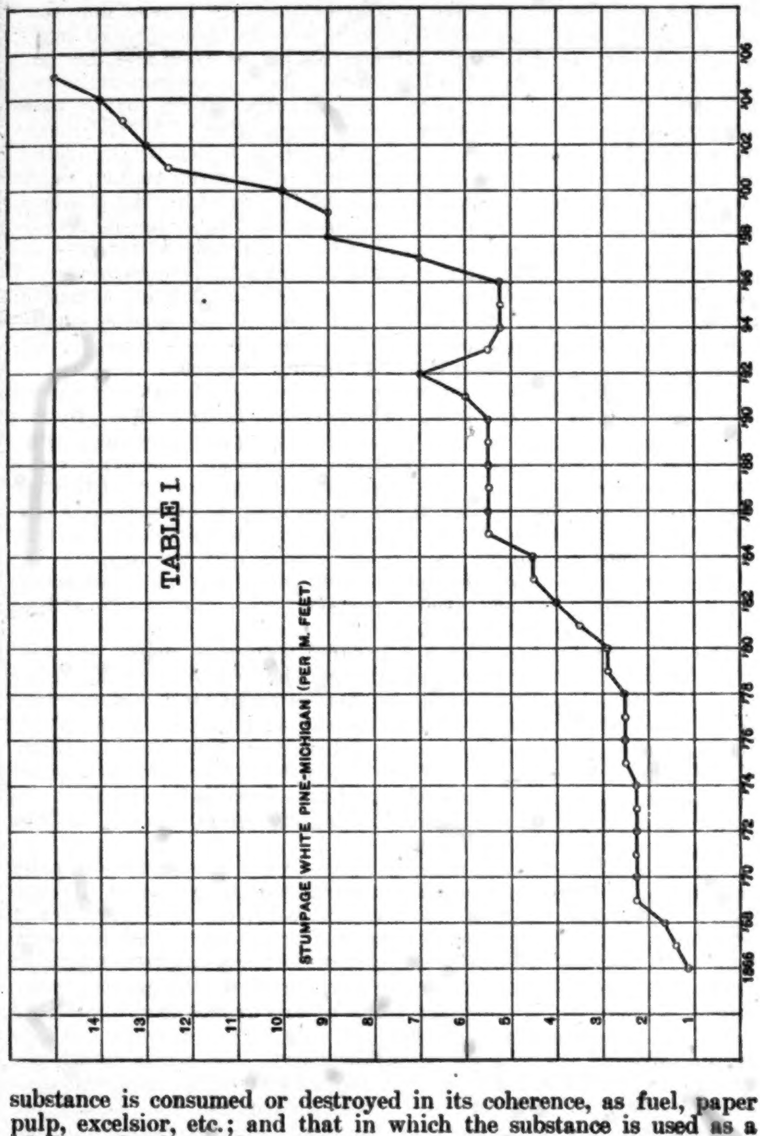

TABLE I

STUMPAGE WHITE PINE-MICHIGAN (PER M. FEET)

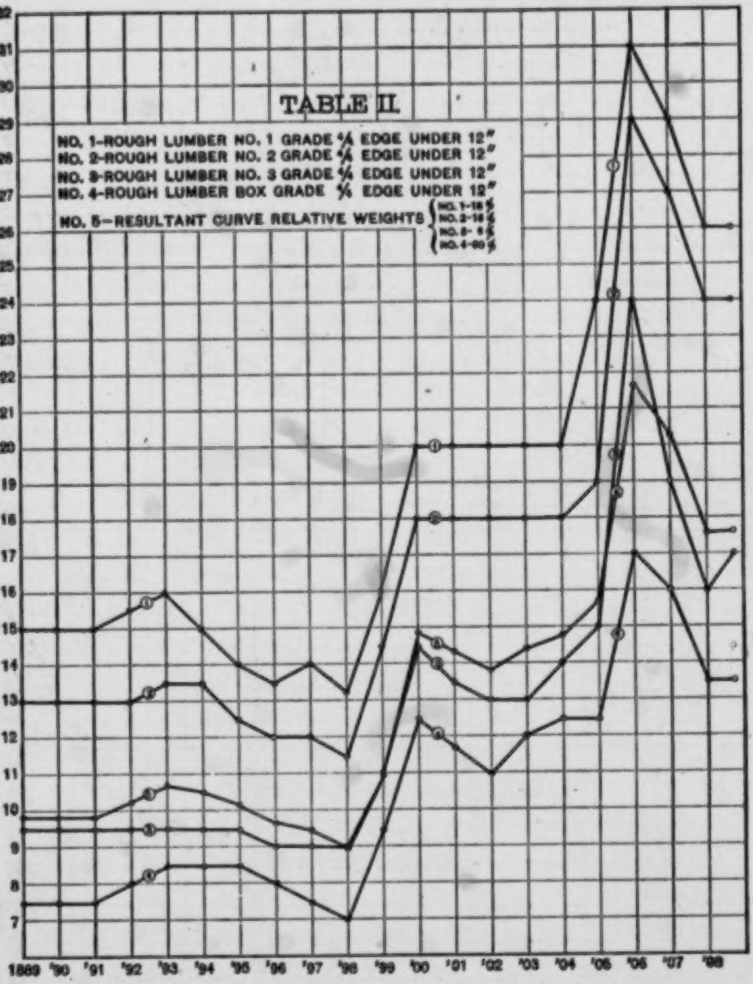
substance is consumed or destroyed in its coherence, as fuel, paper pulp, excelsior, etc.; and that in which the substance is used as a whole, as lumber and construction.

In the first class of uses quality of material, and especially the size, although a requisite, may vary within wide limits; for the second class of uses, more definite qualities, and especially certain size, which in wood is itself a quality, are requisite. Size is a function of age, and the other qualities which make satisfactory logs for lumber manufacture, namely, clean materials, free from loose knots and small taper, are also in part results of age. Hence this use of wood and this portion of the forest growth, the log timber, is the more important one, and here the time element enters prominently, which makes wood from the economic point of view a material peculiar to itself, different from any other product, owing to the long time which its production requires. As a consequence, we may find for a given region, as for instance in Massachusetts, that the price of fuel wood has not changed, or, if anything, has decreased, while that of saw timber has increased; the reason being that the local supply of material only fit for firewood has become relatively greater since the cut-over lands were robbed of the old timber and young or inferior growth has become a general feature. Similarly, we will find the prices of the best-quality lumber varying in a different manner from those for inferior grades, the latter as a rule being in oversupply and sagging in price.

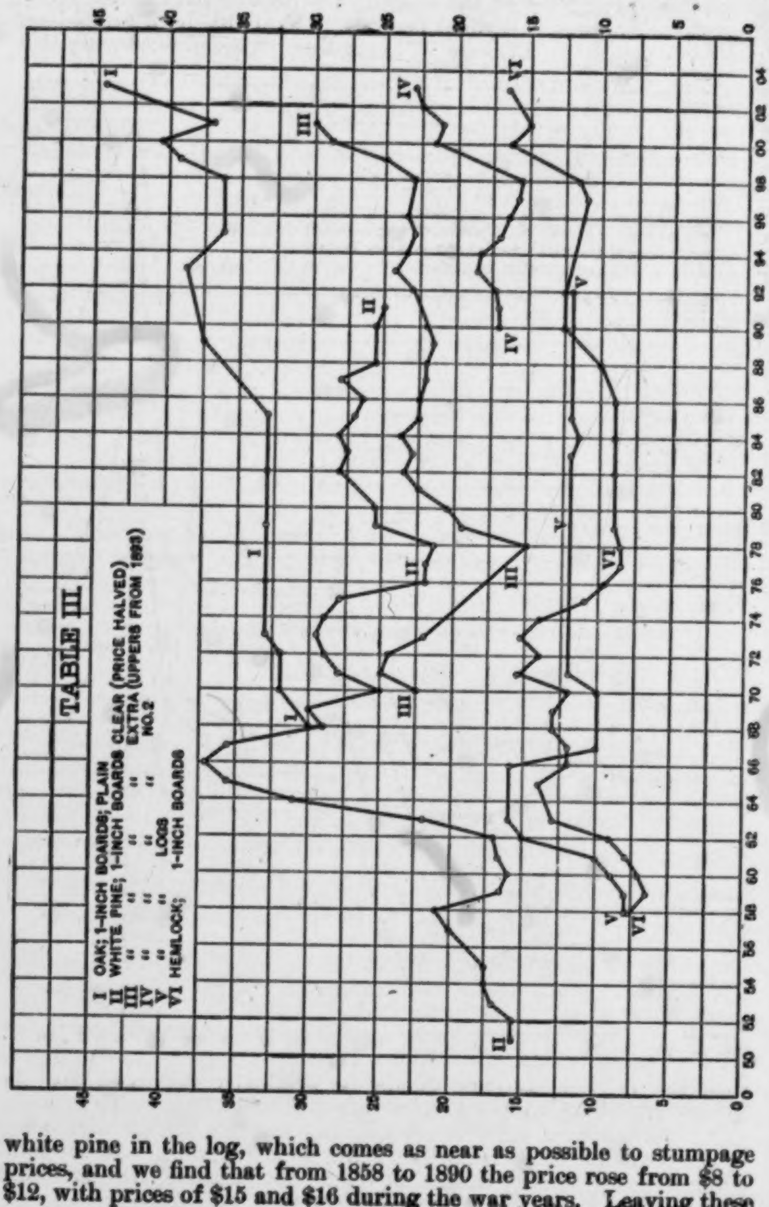
Again, the importance and hence the quantity of consumption of different kinds of wood varies. The soft woods, and especially the conifers, answering the greatest variety of purposes, are the largest and most important requirement of our civilization, the hard woods being less prominent in our consumption in the proportion of three to one. Hence, although prices of the latter may be higher, their economic importance is, generally speaking, inferior to that of conifers, especially when we survey the world's sources of wood supply. We must not class the large amount of hard, beautiful, tropical woods, which are mainly for ornamental purposes, with our structural timber supply of the Temperate Zone.

The price of lumber does not parallel stumpage prices, the tendency being to more uniform and relatively lower lumber prices, owing to continental competition in the market, as well as to the cheapening of processes of manufacture, of trade, and of transportation. There are also other factors which assist in bringing about this condition, viz., the increased utilization of top logs and the decrease in diameter of cutting, as well as the use of logs formerly culled and left in the woods, thus throwing on the market a very great amount of low-grade, low-priced lumber.

Moreover, the different grades of lumber vary considerably in price and fluctuate differently, so that it is difficult to get at an average price. This is very aptly shown in Table II, where is graphically presented the rise in price of four grades of North Carolina pine from 1889 to 1908. It will be noted that the curves representing each of the four grades follow each other very closely in the general trend, though, as may be expected, the prices of low grades tend to advance slowly and high grades very rapidly, due to the growing scarcity of high-grade logs. In the resultant curve (No. 5) is shown the average price of the four grades, the grades being given the relative weights of 18 per cent for No. 1 grade, 16 per cent for No. 2, 6 per cent for No. 3, and 60 per cent for box. This proportion for all the years, however, is not a correct one, but will serve in giving a general indication of the selling price for the total product. To be more correct, a higher relative weight should be given the higher grades in the first decade and a correspondingly lower weight to the low grades, since at this time there was a greater percentage of high-grade logs coming out of the woods. During the past decade, however, there has been a gradual decrease in available high-grade logs, and consequently an increase in low grade. Therefore, during this time the relative weights should be gradually decreased for the higher grades of lumber and increased for the lower. This would make the resultant curve higher during the first decade and lower in the second, thus showing that while the average price of the total product has gradually increased, it has not been so great as would appear from the resultant curve presented.



Nevertheless, when prices of lumber of all grades rise steadily the ultimate cause may be sought in the increased cost of raw material. In Table III we have a short but significant series of prices for



white pine in the log, which comes as near as possible to stumpage prices, and we find that from 1858 to 1890 the price rose from $8 to $12, with prices of $15 and $16 during the war years. Leaving these latter excessive rates out of consideration, the rise during the thirty-two years appears to be at a rate of not much more than one-half of 1 per cent. Hemlock logs rose during the same period from $6 to $8, or at the rate of about 1 per cent; white-pine lumber, 1 inch clear, on the other hand, rose from about $30 in 1840 to $50 in 1891,

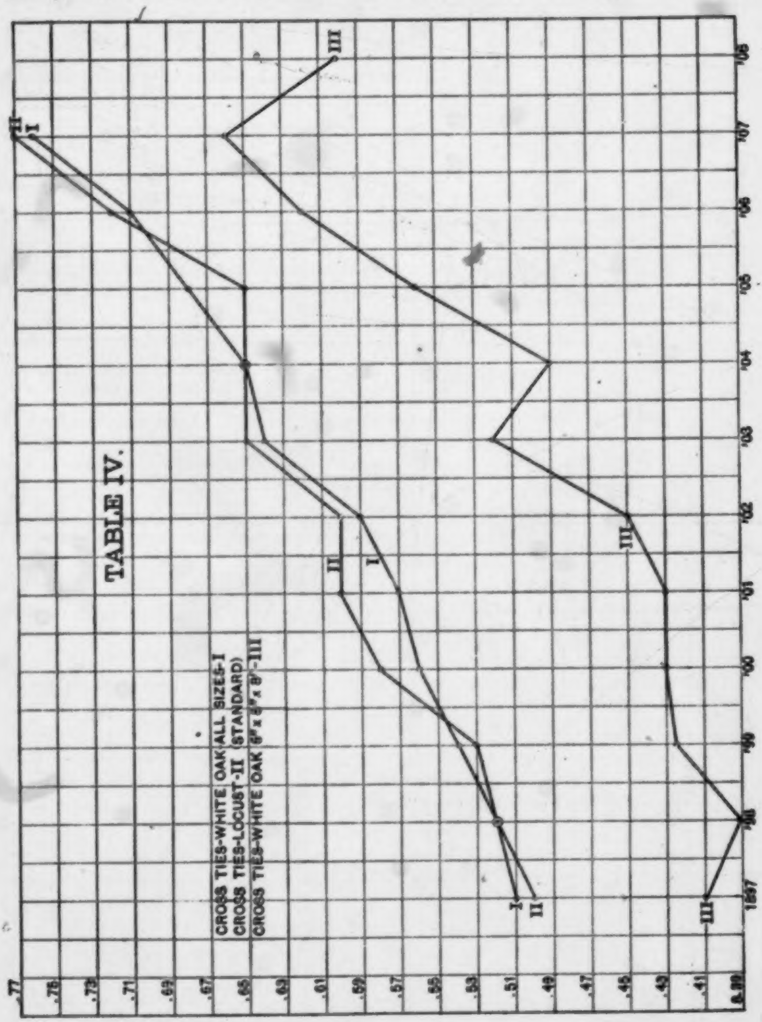


TABLE IV.

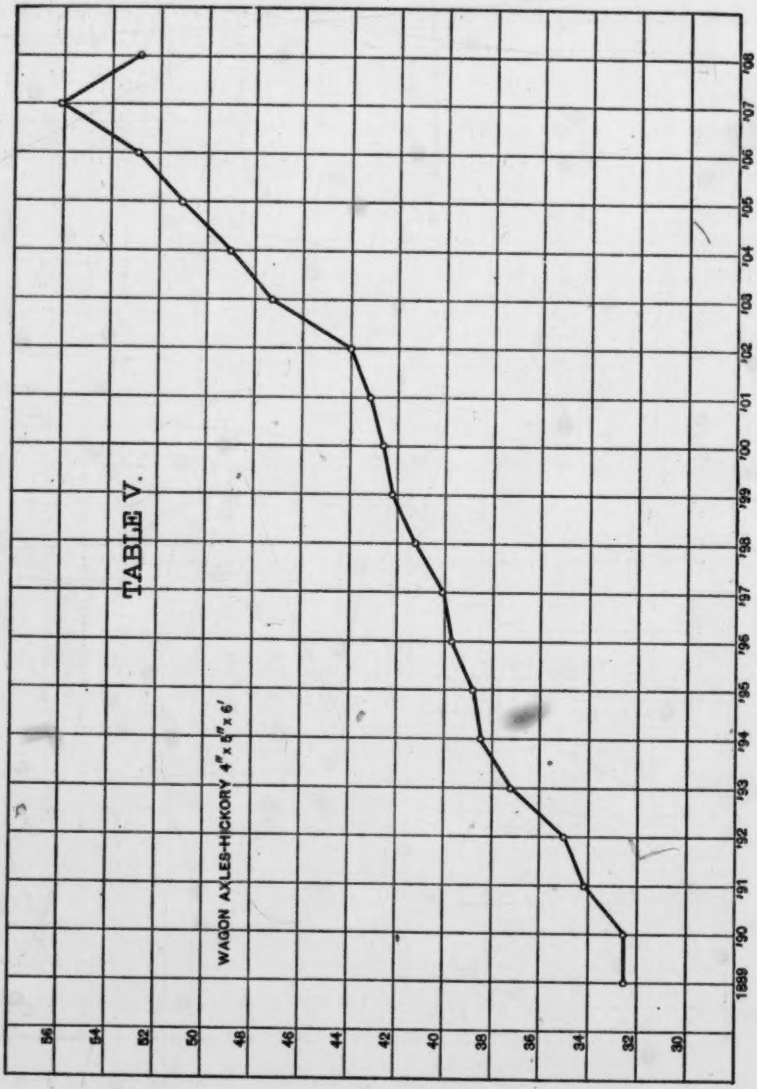
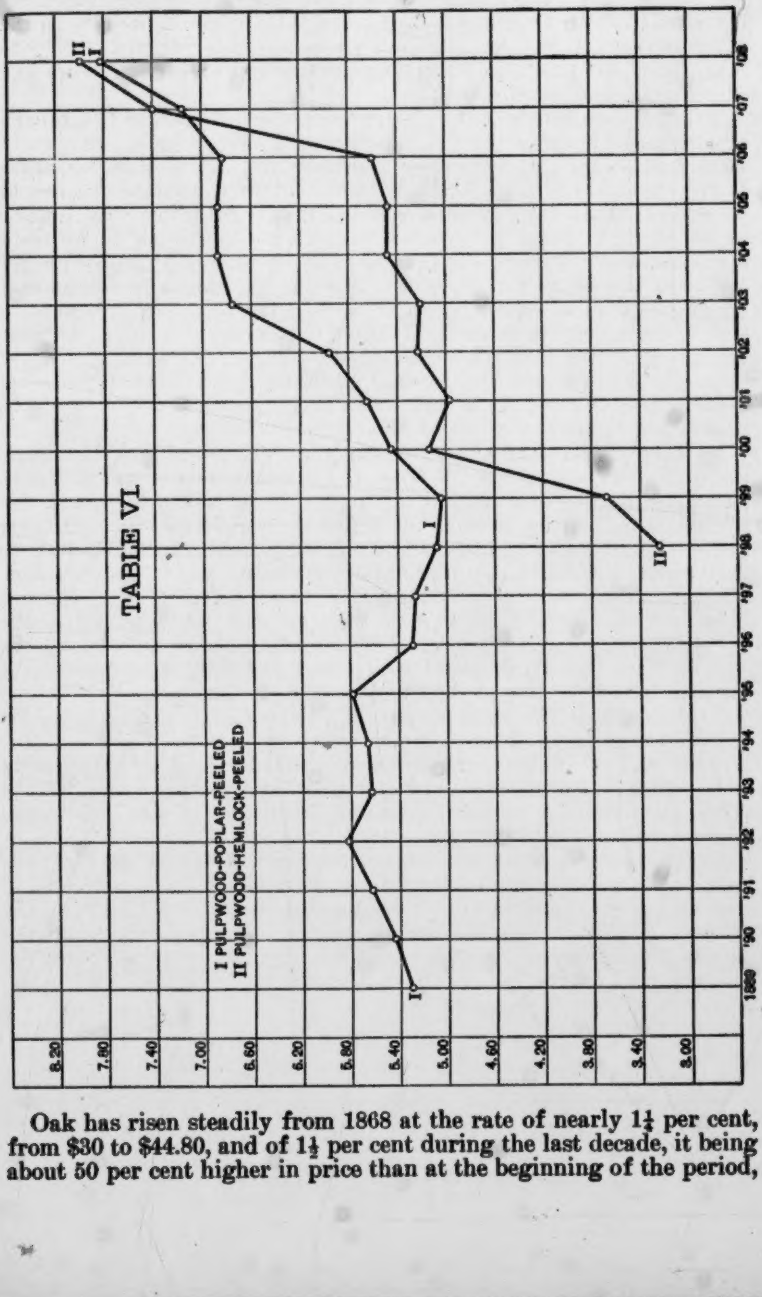
or at the rate of 1 per cent, but from 1890 to 1900 the rate of rise in uppers was from $44 to $57.50, or 2¼ per cent, while from 1900 to 1903 a phenomenal rise to $80, or at the rate of over 6 per cent, has taken place. At the same time the price of number two, 1-inch boards, rose from $16.80 to $24, or at the rate of 2½ per cent. The change in quality appears in the two converging curves of the earlier period, the quality uppers combining the two after 1890. It is now well known that the end of white pine as a great lumber staple is near



at hand, and hence this sudden rise, but the price of other woods also has risen, although not quite so rapidly. For hemlock inch boards the rate during the last twenty-five years has been 2¼ per cent, and during the last ten years 3½ per cent, namely, from $12 to $16.80, and if we go back forty-five years and leave out of consideration the influence of the war years, the increase has been at the rate of 1¾ per cent per year.



Oak has risen steadily from 1868 at the rate of nearly 1¼ per cent, from $30 to $44.80, and of 1½ per cent during the last decade, it being about 50 per cent higher in price than at the beginning of the period, thirty-five years ago. Yellow pine, of which large supplies are still in sight, has shown little change, having in the last fourteen years hardly moved upward, although fluctuating $4 and more within that period. This evenness of price is due probably to the rapidly increasing competition among mill men in the southern section of the country, for it is well known that stumpage prices have, especially in the last ten years, grown at an almost incredible rate, stumpage of pine being held now at from $2 to $3 per thousand which ten years ago was bought for 50 cents to $1.

We may then conclude that as far as lumber prices reflect stumpage prices, these, even in the United States, in spite of the apparently large home supplies, have risen suddenly and are now rising much faster than in the period before 1890. In fact, we have reason to believe that stumpage prices are rising relatively faster than lumber prices, for the latter have a tendency to be depressed, as we have stated before, by trade competition and by new supplies becoming available and being thrown on the market, the necessities of the case forcing mill men, especially in times of industrial retrogression, to accept inadequate pay, while timber-land owners can afford to wait for improvement in market conditions.

In addition to prices of lumber and stumpage, there is also presented with this report a series of curves showing the increase in price for a number of years of other forest products.

In Table IV is shown the increase in cost of cross-ties. It will be noted that the curves for all sizes of white-oak and standard locust ties show no decrease during the past decade, while the curve for white-oak 6-inch by 8-inch by 8-foot ties reflect both the overproduction of material in 1903 and the business depression of 1907–8. The reason for this latter reflection is probably due to the fact that the 6-inch by 8-inch by 8-foot oak ties constitute the bulk of the ties used and therefore react closely with general business, while the curves for locust and all sizes of white-oak ties were held up by the cost of higher-grade material which does not readily respond to a general depression due to the decrease in their demand.

In Table V is shown the increase in the cost of hickory wagon axles. Being made from a wood which is highly prized for this purpose and which is constantly decreasing in supply and increasing in demand, no overproduction has resulted and the price has steadily increased until the general financial depression of the past year, when it fell off slightly.

In Table VI is presented the prices of hemlock and poplar pulp wood. The same general fluctuations are noted in these curves as in the preceding ones, with the exception that in the past few years the scarcity of future supplies has made itself markedly felt and the price has continued to advance most rapidly, not even reflecting the last financial depression of 1907–8.

LANDS, MINERALS, AND NATIONAL VITALITY

CROP YIELD PER ACRE.

By V. H. Olmsted,

Chief of Bureau of Statistics, United States Department of Agriculture.

In compliance with the request of the commission for information regarding the average yield per acre, by decades, of certain leading representative agricultural crops of the United States, to be used in answering one of the inquiries propounded by the executive committee of the National Conservation Commission, I hand you herewith three statements, marked "A," " B," and " C," respectively.

The statement marked "A" shows the average yield per acre for the decades 1867–1876, 1877–1886, 1887–1896, and 1897–1906, of nine of the principal crops, to wit, corn, wheat, oats, barley, rye, hay, buckwheat, potatoes, and cotton, for each State and Territory, with the total average yield for the same decades for the United States of each crop.

The statement marked " B " shows the average yield per acre in the forty years 1867–1906, and the average yield in each decade for the same crops covered by the statement marked "A," in the United States as a whole.

The statement marked " C " compares, in percentages, the average yield per acre of the crops in question in each decade with the average yield per acre for the entire forty years, the yield for the whole period being represented by 100.

The inquiry to which these figures are given in reply, taken in connection with its subinquiries, is apparently based on the presumption that there has been, and is constantly going on, a diminution in the average productivity of the soil.

A perusal of the figures submitted shows such presumption to be erroneous. A brief glance at the statement marked " C " will convince one of this fact, as it stands out with great plainness that during the decade ending with 1906 there was a substantial increase in productivity as compared with the entire forty-year period. This is not true of a single crop only, but of every crop covered by the statement, and were it possible to give exhaustive figures regarding many other crops the same results would undoubtedly be shown.

That there should be an increase instead of a decrease in the soil productivity might be expected when the work which has been carried on by the Department of Agriculture is taken into consideration, particularly during the last dozen years. It would be strange, indeed, if all the work of this great department should result in no advantage to the agricultural interests of the country.

A brief mention of some of the lines along which the betterment of agricultural industry has been accomplished by the Department of Agriculture may not be out of place in this connection:

The Bureau of Plant Industry, whose ramifications extend to every section of the country, is constantly teaching the farmers how to improve their crops by breeding and selection; how to put into operation the best methods of farm practice; and how to prevent diseases in plants. It is constantly securing and distributing new and improved varieties of seeds and plants; studies and disseminates information as to their adaptability to the various sections of the United States, and is continuously carrying on the enormous work which must, in the very nature of things, result in vast improvement in agricultural conditions.

The Bureau of Soils investigates soils in their relation to crops; their adaptation to crops; their proper utilization and management; and information is disseminated in relation thereto, to which all farmers have access.

The Office of Experiment Stations represents the department in its relations to the agricultural colleges and experiment stations scattered throughout the length and breadth of the United States. In these experiment stations ocular demonstrations are given of the best methods of cultivation and of the best varieties for the cultivator.

The Bureau of Entomology obtains and disseminates information in regard to injurious insects affecting field crops, fruits, truck crops, forest, and forest products, etc., and gives instructions as to the best methods for their suppression or the prevention of their ravages.

The Bureau of Biological Survey investigates the economic relations of birds and mammals which are beneficial to agriculture, and also of those which are destructive.

The Bureau of Chemistry makes such investigations and analyses as pertain in general to the interests of agriculture, dealing with fertilizers and agricultural products.

The Weather Bureau gives timely warning by the display of weather and flood signals, and issues storm warnings for the benefit of agriculture, which information enables farmers to adopt measures for the protection of their growing crops or those already harvested.

The beneficial effects of the work of these bureaus, and of the Department of Agriculture generally, are clearly shown by the figures covering the last decade, during which their operations have been actively and widely extended.

The agricultural resources of the country have been, and are constantly being, conserved by the Department of Agriculture; and it is impossible to estimate in terms of dollars and cents the enormous benefit that has accrued to the farmers of the United States through the operations of this department. The amount of money which has been expended by it under congressional appropriations is a mere bagatelle when compared with the amount gained by the people through its operations.

A.

CROP YIELD AND SOIL COMPOSITION.

By Dr. Milton Whitney,
Chief of Bureau of Soils, United States Department of Agriculture.

THE FERTILITY OF THE SOILS OF THE UNITED STATES AS MEASURED BY THE YIELDS OF CROPS.

At the recent conference at the White House on the conservation of our natural resources, Mr. J. J. Hill gave very forcible expression to an idea which is quite commonly held, that the fertility of our soils is being reduced and that they are becoming exhausted. He used three illustrations to prove the point, namely, the yield per acre of wheat in the States of New York, Kansas, and Minnesota. In New York the average yield for the past ten years, he states, is about 18 bushels; during the first five years of this period the yield was 18.4 and during the last five years 17.4 bushels, apparently showing an alarming decrease during a comparatively short time. If, however, he had gone further back into the official records of the Bureau of Statistics of the Department of Agriculture, he would have found that the average yield of the State of New York for the past forty years (1866–1907) is 15.7 bushels, the average yield for each decade since 1866 being 14.1, 15.6, 15.4, and 17.9, indicating an apparent increase instead of a decrease with the average acreage for each decade of 592,584, 743,209, 547,191, and 452,204.

In like manner he called attention to the fact that the average yield for the past ten years in Kansas was 14.16 bushels. For the first half of the period the yield was 15.14 bushels and for the last half 13.18, but the department records show that the average yield for Kansas for the past forty years is 13.9 bushels, so that on the face of it his argument again falls down, but in this case there is another factor which did not enter markedly in the case of New York, namely, that the acreage upon which the estimates of the yield per acre is made has materially changed. The average yield of the four decades is 15.0, 13.6, 12.7, and 14.2, and the acreage for the corresponding decades 372,788, 1,617,317, 2,523,637, and 4,818,335. The development of agriculture in Kansas, as expressed in the increase of nearly 1,200 per cent in wheat acreage, has been in the direction of the semiarid portion of the State and on lands which were formerly not considered suitable for cultivated crops, so the indications are certainly strong that the fertility of the Kansas soils, as expressed by the average yield of wheat, has not declined in the past forty years.

In the case of Minnesota he states that the average yield for the past ten years was 12.96 bushels. For the first half of this period the yield was 13.12 and for the last half 12.8. But the average yield of wheat in Minnesota for the past forty years was only 13.6 bushels. The yield for each decade was 14.4, 13.4, 13.7, and 13.0, with an acreage of 1,309,367, 2,705,898, 3,130,794, and 5,281,253, giving another case where the area upon which the average yield is estimated has been considerably increased.

YIELD PER ACRE OF WHEAT IN THE UNITED STATES.

A careful study of the official records of the Bureau of Statistics of the Department of Agriculture fails entirely to bear out the general impression that the yields are declining in the United States as a whole or in any considerable portion of the area, but on the contrary indicates strongly that the yields as a whole are increasing, although to a slight extent. It is, of course, extremely difficult to draw conclusions from estimates, even with records extending over a period of forty years, in a country which has been rapidly developing and when the basis of the estimates, namely the area, is rapidly increasing and where the seasonal variations are large.

The average yield of wheat in the United States for the past forty years is 12.7 bushels. The four decades show 12.0, 12.5, 12.7, and 13.8, indicating an apparent regular increase in productivity, but at the same time the acreage has increased 21,661,078, 35,060,189, 32,623,809, and 45,540,593, so that it is not safe to draw this inference from the figures above. There are 33 States which have a higher average yield per acre than the United States as a whole and 15 having a lower yield. If proportionately more of the increase in acreage has occurred in the 33 States having above the average yield for the country as a whole, the increase in yield per acre for the United States would be accounted for. This line has not been followed out as it is obvious that we must look further into the facts before any safe conclusions can be drawn as to any change in the fertility of our soils.

AVERAGE YIELD PER ACRE OF WHEAT IN THE SEVERAL STATES.

In the following table the States for which the Bureau of Statistics has full forty-year records (except California, which has records extending over only thirty-nine years) are arranged in the order of the average yield per acre of wheat over this period.

Average yield of wheat, in bushels per acre, for forty years, 1866–1907.

State.	Yield.	State.	Yield.	State.	Yield.
Vermont	18.5	Maryland	13.3	West Virginia	10.6
Maine	16.5	Illinois	13.2	Kentucky	10.5
New York	15.7	Nebraska	13.1	Virginia	9.1
New Jersey	14.5	Indiana	13.1	Arkansas	8.9
Michigan	14.5	Delaware	13.1	Tennessee	8.2
Pennsylvania	14.2	California	12.9	Mississippi	8.1
Ohio	14.1	United States	12.7	Alabama	7.6
Kansas	13.9	Iowa	12.4	Georgia	7.1
Wisconsin	13.7	Missouri	12.2	North Carolina	6.9
Minnesota	13.6	Texas	11.5	South Carolina	6.6

The most obvious fact brought out by this table is that the arrangement shows roughly three geographical groups of States, the Southern States having very small yields, the New England States with New York showing the largest yields (from two to three times as large as the Southern States), and the great wheat States of the Middle West coming in between.

This great difference between the States will be considered later; what concerns us now is the variation in the yield per acre for any particular State or group of States. The average yield for each of the four decades is given in the table prepared by the Bureau of Statistics for each of the States. These yields show a general tendency to increase, but there are fluctuations which make it difficult to draw satisfactory conclusions as the seasonal variations have not been entirely eliminated even over so long a period, and we know that great changes have occurred in the acreage of certain of the States; it is important to see the effect, if any, upon the average yield.

In considering the question of change in the fertility of the land as measured by the yield per acre of crops, it is necessary to have records covering a sufficiently long period to reduce the seasonal variations to a very small amount, and it is unfortunate that we have not available continuous records in this country for more than forty years, either for a State or for any individual farm or constant area of any soil type.

NEW ENGLAND STATES AND NEW YORK.

The nearest approach to this constant acreage and uniformity of yield in several States, where at the same time records of the Bureau of Statistics are available for forty consecutive years, is in what may be taken as two groups of States, namely, Maine, Vermont, and New York; and New Jersey, Pennsylvania, Delaware, and Maryland. In all of these States agriculture is old and in the past forty years there has been relatively very little new land to take up.

In Maine and Vermont the acreage in wheat, at all times small, has been reduced considerably in later years, and the yield per acre has materially increased during the successive decades. It may be argued that this increase in yield per acre is due to the abandonment of the lands less well adapted to wheat, but in New York, with a very much larger acreage but with a much smaller difference in acreage, the yield has increased nearly as much. If we take the figures representing the yield per acre for each of the States for the four decades as an indication only of fertility and regardless of acreage and add them together, we get a factor of relative productivity for the different decades in which the seasonal fluctuations will be more nearly eliminated than if we had used the weighted averages, and while the results show the same order of increase we get a smoother curve.

Reducing these sums to figures approximately equal to the average yields per acre of the several States, by dividing by the number of States, the relative yields of the several decades are represented by the figures 14.6, 15.6, 17.4, and 20.5, indicating a decided and progressive increase in the productivity of the lands.

These States, however, show a remarkable falling off in the total land values and contain many so-called "abandoned" farms, but so far as the production of wheat is concerned this is not due to a decline in fertility or the wearing out of the soil, and the explanation must be sought in changed economic conditions connected with the relative cost of production and other conditions which are outside of the scope of this article.

NEW JERSEY, PENNSYLVANIA, DELAWARE, AND MARYLAND.

The effect of the intelligent reduction of acreage mentioned as a possible factor in increasing the yield per acre of wheat in the New England States and New York can not hold with equal weight with the second group of States above mentioned, as the acreage has varied but little in the States of New Jersey, Pennsylvania, Delaware, and Maryland. Nevertheless by combining the yields per acre as fertility factors for these States, as was done in the last group, the relative order of productivity for the different decades is represented by the figures 12.7, 12.9, 13.4, and 16.0, again showing a regular increase for a group of some of the older States, where the land has practically all been settled for much longer than the forty years.

VIRGINIA, NORTH CAROLINA, SOUTH CAROLINA, GEORGIA, AND ALABAMA.

In these States the average yields per acre have been closely comparable and the acreage not very different either among the States or during the period of forty years. In each case there is an indication of a slight increase of productivity, although both the first and last decades show larger yields than either of the intermediate ones. The relative order of the group of States for the four decades is represented by the figures 7.4, 6.8, 6.9, and 8.7.

OHIO, INDIANA, AND ILLINOIS.

Ohio, Indiana, and Illinois form another group of States having nearly the same acreage and the same yields per acre in which the yield per acre for the past forty years has apparently at least held its own or even increased, the relative productivity of the three States for the four decades being represented by the figures 11.9, 14.2, 13.5, and 13.9.

WISCONSIN, MICHIGAN, IOWA, AND ILLINOIS.

We come now to two groups of States showing some marked differences in acreage in the last forty years. The sum of the average acreage in wheat for the four decades in the first of these groups (Wisconsin, Michigan, Iowa, and Illinois) is 7,330,041, 8,525,988, 5,697,582, and 4,572,012. The relative yield per acre of the group of States for the corresponding decades may be expressed by the figures 12.4, 13.3, 13.8, and 14.3.

It may be argued, as in the case of the New England States, that in restricting the acreage the lands less well adapted to wheat have been first abandoned and the average yield increased in this way.

MINNESOTA, NEBRASKA, KANSAS, AND MISSOURI.

We have another group of closely adjacent States, namely, Minnesota, Nebraska, Kansas, and Missouri, where the sum of the mean acreage for the several decades has been 2,693,576, 7,799,182, 8,654,331, and 14,364,930, while the relative yield per acre of the group may be expressed by the figures 13.8, 12.6, 12.6, and 14, again an apparent increase. The figures for Minnesota and Kansas, it is true, appear to show a slight decrease, but the seasonal variations in both these States are large, so large they are not eliminated in the ten-year periods. For example, in Nebraska in the first and third decades the difference between the highest and lowest yield is actually greater than the average yield for forty years. The larger the groups of States that can be compared, therefore, the better. The relative yield per acre for the eight States in this and the preceding group for the several decades may be expressed by the figures 13.1, 12.9, 13.2, and 14.1. From the data available it is reasonable to assume that the yield per acre in each of these states has increased to some extent, although in four of the States the acreage has increased and in the other four it has decreased.

KENTUCKY AND TENNESSEE.

Kentucky and Tennessee, each with an acreage fairly constant, show an increase in yield per acre, while West Virginia has remained about constant.

OHIO, WEST VIRGINIA, AND INDIANA.

Ohio, West Virginia, and Indiana, with an increasing acreage for the first three decades, represented by the figures 3,503,127, 5,283,871, 5,530,392, and 4,588,086, show a slight increase in fertility, represented by the figures 11.6, 13.3, 12.4, and 13.1.

TEXAS AND ARKANSAS.

Of the other large wheat-producing States, Texas, with an increase of acreage from 119,340 acres in the first decade to 993,206 in the last, has remained practically constant in yield per acre, while Arkansas, with a practically constant acreage, has increased during the past thirty years.

CALIFORNIA AND OREGON.

California, with a fairly constant acreage, is the only one of the States showing an apparent decline in yield per acre, the figures for the several decades being 14.6, 12.9, 12.7, and 11.6. But, it should be observed that during the last decade there occurred two of the lowest yields on record, while in the last year of the last decade the yield per acre was 17.1 bushels, exceeded only by the crop of 1868 of 20 bushels and that of 1870 of 19 bushels. The two middle decades in many of the States show lower yields than the first and last, which indeed is shown in the adjoining State of Oregon, where the yield by decades is 18.6, 17.1, 17.1, and 18.7, and the fact that in the last year of the last decade a yield was obtained exceeded only by two others, makes it seem quite probable that with more data covering a longer period of time California would show no exception to the rule of a slight but gradual increase in productivity as measured by the yield per acre of wheat.

The following table gives the data for the States having records covering less than forty-year periods and more than twenty years, and with not less than five years in each decade:

Average yield of wheat, in bushels per acre, in States having twenty to forty year records.

State or Territory.	First decade.	Second decade.	Third decade.	Fourth decade.
Utah		[a] 17.5	18.8	22.5
Nevada	[b] 21.1	[b] 17.8	19.2	26.9
Wyoming		[a] 17.4	[c] 21.0	23.0
Idaho		[a] 16.9	19.2	23.8
Colorado		[b] 19.2	19.0	24.6
North Dakota		[a] 14.1	[c] 14.0	12.3
Montana		[a] 17.5	20.8	26.7
New Mexico		[a] 13.2	15.6	20.0
Arizona		[a] 13.8	16.2	21.8
Washington		[a] 16.5	17.7	23.3

[a] 5 years. [b] 7 years. [c] 6 years.

The data here are so incomplete in comparison with what has been given, and the question of irrigation in many of these States introduces so uncertain a factor, that the results will not be discussed; while for some of the other States, notably New Hampshire, Massachusetts, Connecticut, Rhode Island, South Dakota, Louisiana, and Florida, the data are so incomplete that no conclusions can be drawn.

If any conclusion is to be drawn from the statistics it can only be that the fertility of our soil, as measured by the average yield of wheat per acre, is increasing.

YIELD PER ACRE OF CORN IN THE UNITED STATES.

The average yield per acre of corn in the United States for the past forty years is 25.1 bushels, the figures for the four decades being 26.1, 24.8, 24.2, and 25.4. It is apparent that the period of forty years with its four decades is too short a time to eliminate or balance the great seasonal variations, and in the country as a whole as well as in the records from most of the States we get a yield above the average in the first and last decades and below the average in the two middle periods. It would appear, then, on the face of it that there has been no decline in fertility as measured by the yield per acre of corn, but it must be remembered that the acreage upon which the estimate of the yield is made has considerably increased, the figures for the several decades being 386,884,000, 634,089,000, 742,909,000, and 879,712,000.

As the estimated average yield per acre is based upon the actual acreage in corn, it is obvious that if the greater portion of this increased acreage occurred in the States having greater average yields than the country at large, the average yield of the United States would be increased, possibly to the extent of masking any change in the fertility, while, on the other hand, if the greatest increase in acreage occurred in the States having a lower average yield, the average yield per acre of the United States would be reduced, so that in themselves the figures above given show nothing as to any change in fertility of the soil of the United States. To arrive at any definite conclusion it will be necessary, as in the case of wheat, to consider the yield of individual States and of groups of States. It may be stated at the outset, however, that for two reasons the figures for corn do not lend themselves so well to a complete solution of this great question as do those for wheat. The average yields per acre of nearly all the States are considerably higher in the first and last decades than in the intervening twenty years, indicating probably profound and long continued seasonal variations.

The acreage in all but New York, Pennsylvania, and California of the large corn-producing States has increased considerably, and in only two of the smaller States, namely, Rhode Island and Maine, has there been a regular and obvious reduction in acreage, so that the influence of intelligent selection of lands to be taken up or abandoned for corn culture can not be considered. However, in the case of wheat it was shown that this had no apparent effect upon the average yields so far as could be determined from the statistics.

YIELD PER ACRE OF CORN IN THE SEVERAL STATES.

The following table gives the States for which forty consecutive years' records are furnished by the Bureau of Statistics, excepting California, which has thirty-nine years' record, arranged according to their average yields per acre:

Average yield of corn, in bushels per acre, for forty years, 1866–1907.

State.	Yield.	State.	Yield.	State.	Yield.
New Hampshire	35.1	Michigan	30.8	Delaware	22.6
Vermont	35.1	Illinois	30.2	Tennessee	22.0
Massachusetts	34.5	Rhode Island	30.1	Arkansas	20.0
Pennsylvania	33.2	California	30.1	Texas	19.1
New Jersey	33.2	Minnesota	29.2	Virginia	19.0
Maine	32.9	Nebraska	28.7	Louisiana	16.7
Ohio	32.9	Missouri	28.3	Mississippi	15.0
Connecticut	32.2	Maryland	26.6	North Carolina	13.3
Iowa	32.2	Kentucky	26.1	Alabama	13.1
Indiana	31.5	West Virginia	25.3	Georgia	11.0
Wisconsin	31.3	Kansas	25.1	Florida	9.8
New York	30.8	United States	25.1	South Carolina	9.7

There are twenty-three States having the same or a higher average yield than the United States and twelve States having a lower yield.

It is obvious that the yield per acre remaining the same, any increase in acreage will have no effect on the average yield for the United States, while an increased acreage in Georgia would counterbalance an increase of nearly three times the acreage in Nebraska, on account of the disparity in the yield and the departure from the average. It has not been deemed wise, however, to attempt to arrive at conclusions as to a change of fertility by such a method of comparison.

NEW ENGLAND STATES.

The acreage in Maine and Rhode Island has materially decreased, while indications are that the yield per acre has slightly increased. The acreage of the four other States has remained fairly constant, while the figures indicate a slight decrease in the yield per acre in New Hampshire and Vermont and a slight increase in Massachusetts and Connecticut. The differences, however, are so slight, as compared with the fluctuations between the decades, that no safe conclusions can be drawn as to any change of fertility. Comparing the groups of States, as was done in the case of wheat, the acreage for the four decades was 2,469,000, 2,627,000, 2,169,000, and 1,951,000, while the relative yields for the four decades may be expressed by the figures[*] 32.6, 32.5, 34.4, and 34.2, indicating if anything a slight increase in fertility of the soils as measured by the yield per acre of corn.

NEW YORK, PENNSYLVANIA, AND NEW JERSEY.

The acreage in New York, Pennsylvania, and New Jersey, has varied but little in the forty years, and the average yields indicate neither an increase nor decrease.

MARYLAND, DELAWARE, AND VIRGINIA.

The relative yield in the four decades of Maryland, Delaware, and Virginia may be expressed by the figures 21.8, 21.0, 20.9, and 27.0; the total acreage being 16,145,000, 24,973,000, 28,038,000, and 26,243,000.

NORTH CAROLINA, SOUTH CAROLINA, GEORGIA, FLORIDA, AND ALABAMA.

The relative yield for North Carolina, South Carolina, Georgia, Florida, and Alabama for the four decades may be expressed by the figures 12.3, 10.8, 11.4, and 11.3; the total acreage being 66,993,000, 86,117,000, 102,619,000, and 113,809,000.

OHIO, INDIANA, ILLINOIS, MICHIGAN, WISCONSIN, AND MINNESOTA.

The relative yield for Ohio, Indiana, Illinois, Michigan, Wisconsin, and Minnesota may be expressed by the figures 31.7, 30.2, 29.0, and 33.1; the acreage being 126,441,000, 177,378,000, 162,838,000, and 193,646,000.

So far the data do not permit one to say that there has been an increase in fertility as measured by the yield per acre of corn, save possibly in the New England States, and certainly there is no justification for saying there has been a decrease. We now come to a group of States, however, which show a decided decrease, although a full analysis of the original data does not justify such a conclusion.

NEBRASKA AND KANSAS.

The average yield of Nebraska and Kansas may be expressed by the figures 33.3, 32.5, 25.7, and 24.8. These two States show by far the greatest increase in corn acreage of any of the 35 States under consideration. The basis for the estimate of the average yield per acre in the last decade, namely, the acreage, was 700 per cent larger in Kansas and 2,500 per cent larger in Nebraska than in the first decade, yet we have in Nebraska the average yield of 32 bushels on 3,011,000 acres in the first decade to compare with the average yield of 27.8 bushels on 77,213,000 in the last decade, and nearly as great a disparity in the case of Kansas. The combined acreage for the four decades is 12,625,000, 63,621,000, 110,130,000, and 154,177,000.

---

[*] These figures are straight averages of the yields per acre as fertility factors in which each State has equal weight. This method is only allowed when the acreage and yields per acre of all the States are of the same order or do not vary much. The weighted averages in this case, when the sums of the acres and of the bushels of all the States are used, are 33.1, 32.6, 34.9, 34.6, showing the same order of increase. The former method lends itself rather better for the purposes of this investigation.

However, taking the data as they stand, we find, in going back to the original data, three years of crop failure in Kansas in the third decade, the average yields being for 1887, 14.6 bushels; 1890, 15.6; and 1894, 11.2, the highest yield being in 1889, 35.3 bushels. In the last decade there were three years of very low yields, 1897, 18.0 bushels; 1898, 16.0; and 1901, 7.8. The last five years of the last decade show four years well above the average for the forty years, so that here again there is no apparent justification for assuming a decrease in the average fertility of the soil as measured by the yield of corn. Similarly, in the third decade, Nebraska shows a yield of only 6.0 bushels in 1890, while in the last decade are two very low yields and four out of the last five years show a considerably larger yield than the average for the forty years.

IOWA AND MISSOURI.

Adjoining Kansas and Nebraska on the east are the States of Iowa and Missouri, where there has likewise been a considerable increase in acreage, although not nearly so large as in the first-named States. The total acreage of the two States for the four decades is 58,188,000, 117,138,000, 141,778,000, and 148,721,000. The average yields may be expressed by the figures 31.5, 29.4, 30.3, and 30.2.

MISSISSIPPI, LOUISIANA, TEXAS, AND ARKANSAS.

The average yield of Mississippi, Louisiana, Texas, and Arkansas may be expressed by the figures 20.9, 17.2, 16.9, and 17.5; the total acreage being 40,408,000, 71,225,000, 91,561,000, and 110,791,000. Texas and Arkansas both show a large increase in acreage and a moderate decline in yield, but an analysis of the figures shows reasons for this in great seasonal variations, as in the case of Kansas and Nebraska, and it is not safe to conclude from the data that the fertility of the lands as measured by the yield per acre of corn of any one of these four States has declined. Considering the large increase in acreage and the wide variations in yield per acre due to climatic conditions, it would take a considerably longer period of observations to determine definitely the question of any change in fertility of the soils. In other words, it may reasonably be assumed that for the past forty years the fertility of the soils of this group of States has remained fairly constant.

CALIFORNIA.

The average yield for California may be expressed by the figures 37.4, 28.2, 29.9, and 29.9; the acreage being 326,006, 1,101,000, 1,127,000, and 562,000.

In the last half of the last decade, during four years the average yields were well above the average for the thirty-nine years and are comparable with the yields of the first decade, with the exception of the very large yields of 1868, 45 bushels; 1869, 41.4 bushels; and 1873, 41 bushels; so that it would not be safe to conclude that there has been any decline in the fertility in the soils of the State in the past thirty-nine years as measured by the yield per acre of corn as indicated by the average yields of the four decades, any more than it would be safe to assume an increase during the past thirty years as also indicated by the decade figures.

Summing up the data furnished by the Bureau of Statistics on the yield of corn per acre, it is unsafe to draw any conclusion other than that the fertility of the soil of the United States as measured by the yield per acre of corn has remained practically constant, with, if anything, a slight tendency to increase. The data are, however, much more difficult to draw conclusions from than in the case of wheat, partly because of the wide seasonal fluctuations and partly on account of the large increase in acreage in most of the larger corn States. The following table gives the percentage of increase in the acreage of the 24 States showing an increase, which displays at once the difficulty of drawing conclusions from figures where the basis of the figures which are to be compared has such wide variation:

Percentage of increase in corn acreage from 1866 to 1907 in the several States where material increase has occurred.

State.	Percentage of increase.	State.	Percentage of increase.	State.	Percentage of increase.
Nebraska	2,500	Missouri	130	Indiana	54
Kansas	700	United States	127	Mississippi	50
Texas	356	Michigan	124	Tennessee	49
Minnesota	409	Louisiana	121	Alabama	46
Arkansas	190	Virginia	87	Illinois	36
Iowa	179	South Carolina	85	Maryland	26
Florida	153	North Carolina	75	Ohio	21
Wisconsin	152	Georgia	72		
West Virginia	133	Kentucky	56		

With the full analysis of the data for the two important crops of wheat and corn, it seems unnecessary for the purpose of this report to discuss the data relating to oats, barley, rye, hay, buckwheat, potatoes, and cotton, especially as a casual observation of the data furnished by the Bureau of Statistics on these crops shows the same general facts and would add nothing new to this discussion. The only inference, therefore, which can be drawn from the statistics is that the productivity of the soils of the United States has not declined in the past forty years, but that on the contrary it has increased.

THE FERTILITY OF THE SOILS OF EUROPE AS MEASURED BY THE YIELD OF CROPS.

In considering so serious and fundamentally important a question as the possible loss of soil fertility and the wearing out of our soils, and in order to show conclusively from the data submitted by the

Bureau of Statistics on our crop yields that the common impression on this subject is erroneous, it is well to review the facts presented by the experience of other countries.

In the European countries are older agricultural soils than in the United States, in that they have been settled and have been developing their present agriculture for a thousand years or more, while many parts of our great West have seen all of their agricultural development in the past forty or fifty years, since the great transcontinental railway systems were established.

If the views which have been taught for the past seventy years be correct, that continued cropping gradually exhausts the soil and tends to make it unproductive through loss of mineral plant food, we should expect to find a marked and fundamental difference between the soils of the United States and the older soils of Europe, as shown either in the yield of crops or in the chemical composition of the soils. We will first review such data as are available regarding the yield of crops and then consider the chemical data.

The following is given as the yield per acre of wheat in bushels in several European countries and in the United States for the ten years (1897–1906) in the Yearbook of the Department of Agriculture for 1907, page 620:

Average yield of wheat, in bushels per acre, of various countries.

United Kingdom	32.2
Germany	28.0
France	19.8
Austria	17.8
Hungary	17.6
United States	13.8
Russia (European)	9.3

It is apparent that the older soils of Europe are producing more than the newer soils of the United States. Have they always done so, or are the yields increasing there as they are with us, and has the increase gone farther with the longer time and the greater population and the necessities incident to the larger number of people to support?

Kellermann has made a most exhaustive investigation and report upon the increase in crop production in Germany.[a] He gives the yields per acre of a large number of estates which have been handed down from father to son, some of the records going back to the middle of the sixteenth century. Three cases only will be given here, which show the general trend of the information he was able to gather.

---

[a] Landw. Jahrb. 35, 289 (1906).

Yield of cereals in Schmatzfeld, Germany.

[Reduced to bushels per acre.]

Year.	Wheat.	Rye.	Barley.	Oats.
1552-1557	12.5	13.2	14.2	14.8
1660	......	12.8	8.3	12.3
1670	14.6	17.2	16.1	17.4
1822	18.7	24.3	33.7	26.2
1825	18.1	20.0	28.1	32.5
1830	18.7	21.2	35.6	46.2
1840	25.6	30.0	31.6	45.5
1850	28.7	33.1	39.3	50.1
1860	35.3	39.3	32.9	62.9
1870	27.6	20.4	43.8	46.6
1886	37.9	28.9	43.2	66.6
1887-1896	40.0	29.6	47.6	59.7
1897-1904	45.1	34.0	50.4	69.1

The period from 1552 to 1557, apparently the average for those years, gives a yield of wheat of 12.5 bushels per acre; in 1670 there is a record of 14.6 bushels; in 1822 of 18.7 bushels; in 1825 of 18.1 bushels; in 1840 of 25.6 bushels; in 1850 of 28.7 bushels; in 1860 of 35.3 bushels; in 1897 of 45.1 bushels; an increase in those three hundred years from 12.5 bushels in 1552 to 45.1 bushels in 1897, the record showing a regular increase with a few fluctuations which are probably due to seasonal conditions.

Rye has increased during the same time from 13.2 bushels in 1552 and 12.8 bushels in 1660 to 30 bushels in 1840 and 34 bushels in 1897.

Barley has increased from 14.2 bushels in 1552 or 8 bushels in 1660 to 16.1 bushels in 1670, and finally to 50.4 bushels in 1897.

Oats have increased from 14.8 bushels in 1552–1557, the first record, to 69.1 bushels in 1897–1904, which is the last record.

Yields of cereal crops on a second German estate, Rittergut Trebsen, near Leipzig.

[Reduced to bushels per acre.]

Year.	Wheat.	Rye.	Barley.	Oats.
1756-1765	26.41	15.91	14.25	23.03
1766-1775	13.25	12.33	21.71	23.48
1776-1785	16.63	14.47	20.44	23.45
1786-1795	13.98	13.67	16.77	19.16
1796-1800	13.89	15.36	15.16	17.90
1814-1816	15.28	15.68	25.41	25.72
1820-1822	16.90	19.14	18.28	26.36
1825-1834	21.04	21.63	30.19	31.83
1835-1844	33.40	27.92	36.66	46.54
1845-1849	25.51	28.75	......	56.25
1883-1892	27.03	23.06	30.95	44.64
1893-1894	29.85	28.36	30.95	54.74
1895-1899	35.85	30.45	35.39	51.15
1900-1904	36.14	32.52	43.23	57.80

From this estate apparently even more continuous records are given in five and ten year periods from 1756 to 1904. The average yield of wheat in the first period of which we have a record, 1756–1765, is 26 bushels; in the next period, 1766–1775, it is 13 bushels; and from that time a gradual increase up to 1900–1904, when it was 36 bushels. Rye increased similarly by regular steps from 15.91 bushels to 32.52 bushels. Barley from 14.25 bushels to 43.23 bushels. Oats from 23.03 bushels to 57.80 bushels.

Yield of cereals on the soils of Tellow.

[Reduced to bushels per acre.]

Year.	Wheat.	Rye.	Barley.	Oats.
1800-1810	21.15	14.64	19.80	17.22
1810-1820	20.02	11.76	20.92	13.44
1820-1830	23.25	17.76	21.29	14.84
1830-1840	18.82	15.04	16.37	13.86
1840-1850	23.10	19.84	20.83	27.58
1850-1855	26.40	23.12	32.75	33.46
1855-1860	25.27	24.16	27.71	34.44
1860-1865	29.77	30.48	37.85	44.52
1865-1870	27.45	26.48	36.17	55.72
1870-1875	29.92	28.32	35.71	51.88
1875-1880	28.12	24.32	29.38	39.48
1880-1885	25.57	25.12	36.45	45.08
1885-1894	35.70	29.52	41.06	43.96

On this estate from 1800 to 1894 in ten-year averages wheat increased from 21.15 to 35.70 bushels, rye from 14.64 to 29.52, barley from 19.8 to 41.06, and oats from 17.22 to 43.96.

Kellerman throughout cites many well-known authorities and refers to many sources of information, and concludes his article with this remarkable statement:

> If we now make a brief survey of the results obtained in the foregoing, we must affirm that the development of the yields of cultivated soil since the beginning of the past century presents a very pleasing picture, not only that agriculture, by absolute addition to the acreage of 30 to 35 per cent and decrease in fallow from 35 to 4½ per cent, has tried to meet the growing needs of the nation for food, but above all that it has shown how to gain from the soil gradually 2½ times as much per unit of surface as formerly.

The same facts have been brought out by Steinbrück,[a] who cites many cases of individual farms from records going back for one hundred years or more.

The French minister of agriculture[b] gives the average yield per acre of the principal cereal crops in France from 1815 to 1876, which, reduced to bushels per acre and ten-year averages, is as follows:

Yield of cereals in France.

[Reduced to bushels[c] per acre.]

Year.	Wheat.	Rye.	Barley.	Oats.
1815-1824	11.86	10.10	14.45	17.12
1825-1834	13.44	12.34	14.64	17.78
1835-1844	14.30	13.01	15.92	20.10
1845-1854	15.14	13.09	18.12	22.33
1855-1864	15.90	14.11	19.90	24.93
1865-1874	15.81	14.65	19.75	24.49
1875-1876	16.60	15.71	19.00	23.61

[b] Bull. Min. Agr. Comm. France. Récoltes des Céréales et des Pommes de Terre de 1815 à 1876, pp. 456–459 (1878).

[c] Bushels of capacity. Statistics for the ten years 1897–1906 indicate that the average weight of a bushel of wheat in France is 60.0 pounds, of a bushel of rye 56.1 pounds, of a bushel of barley 49.6 pounds, and of a bushel of oats 36.5 pounds. The statistics for France on p. 39 are in the bushels of weight customarily employed in the United States (wheat 60 pounds, rye and corn 56 pounds, barley 48 pounds, oats 32 pounds). The difference is greatest in oats, the average yield of which, as given in this table, is on a basis some 14 per cent lower than in tables on p. 39, covering later years. Comparisons between these tables should not be made without making allowance for this.

Wheat has increased from 11.86 to 16.60 bushels; rye, from 10.1 to 15.7; barley, from 14.4 to 19; oats, from 17.12 to 23.61. The great increase in the yield of cereal crops for France is prior to 1860.

CEREAL PRODUCTION OF EUROPE.

Quite recently the Bureau of Statistics of this department has published a report on the cereal production of Europe [a] for the past twenty years or so. (See Appendix A.)

The following table as given in this bulletin summarizes the yield per acre as given in detail in the tables in the appendix to this report, in five-year periods.

---

[a] Average, 1896-1899. [b] 1890. [c] 1896. [d] Average, 1892-1895. [e] Average, 1902-1905. [f] Average, 1894-1895. [g] Average, 1886-1890. [h] Average, 1901-1904. [i] 1893. [j] Average 1897-1900. [k] Average, 1897 and 1900. [l] Average, 1896-1898. [m] Average, 1893-1895.

Commenting on this data Rutter has the following to say:

AVERAGE YIELD OF GRAIN.

Wheat.—On comparing the area under wheat in northwestern Europe in 1905 with the average crop during 1901–1905, it appears that the average yield per acre exceeds 25 bushels; in southwestern Europe the average yield is only 16 bushels per acre, and in eastern Europe but 12 bushels. For Europe as a whole the average yield is slightly under 14 bushels per acre.

It appears, therefore, that the average yield per acre is highest where wheat culture is least generally practiced and where the acreage under grain shows the smallest increase. In other words, the extension of the wheat area is most marked where the average yield per acre is lowest.

This condition holds true as regards individual countries as well as the larger divisions of Europe. The United Kingdom, Belgium, the Netherlands, and Denmark are at the same time the four countries in which the wheat acreage during the last twenty years has shown the largest reduction and the four countries which show the largest yield per acre. In each of these countries the acreage under wheat has fallen at least one-fifth in amount, while in each of them over 30 bushels per acre has been harvested on an average during the last five years.

At the other end of the series stands European Russia, in which the increase in acreage during the twenty years was no less than 60 per cent, while the average yield per acre was little more than 10 bushels.

Between these two extremes the relation pointed out between yield and acreage has been by no means so constant, but the divergence is not sufficiently marked to affect the general correspondence. In Sweden, for instance, the acreage under wheat has shown a considerable increase, while the average yield per acre is high, nearly 25 bushels per acre. On the other hand, in Spain the low average yield, 13 bushels per acre, has been accompanied by a small increase in the acreage and the crop.

That the extent of wheat culture should vary inversely as the average yield per acre, or, in other words, that where the results are best the smallest areas are devoted to wheat, seems at first sight paradoxical. It must be remembered that a high average yield, such as shown in the Teutonic countries of Europe, presupposes intelligence on the part of the farmers and valuable land justifying a large outlay of labor and capital. These conditions are much more favorable to the growth of crops requiring intensive cultivation than to grain crops, which give the highest profit when grown on new land on a large scale. Low average yields, if obtained at a low cost of production, produce a greater aggregate profit than can be obtained from grain crops on the smaller tracts in northwestern Europe, where the high price of land necessitates its use in intensive culture. (See Table 5. This table contains unweighted averages of the yearly average yields shown later in the detailed tables.)

Rye.—The yield of rye is highest in Belgium, where during the five years 1901–1905 an average of 34 bushels per acre was obtained. After Belgium come Ireland, Denmark, the Netherlands, Norway, and Germany, in all of which an average yield of from 25 to 27 bushels per acre was obtained. The lowest average yield per acre during the same years was obtained in Servia, 10 bushels per acre, while in European Russia the average yield was slightly more than 10 bushels and in Spain 13 bushels per acre.

Barley.—Of barley, as of rye, the highest average yield per acre during the last five years was obtained in Belgium, in which more than 50 bushels per acre was grown on an average, while the average yield of winter barley alone was 52 bushels per acre. In the Netherlands the average yield was only slightly lower, amounting to 51 bushels per acre for winter barley and 48 bushels for barley of both kinds. Outside of these two countries barley is grown principally as a spring crop; and if that variety alone be considered, Ireland, with 42 bushels per acre, shows the highest average yield. In Germany, Denmark, and Great Britain the average yield per acre is 34 bushels. The lowest average yields per acre recorded are shown by the statistics of European Russia and Servia, according to which but 14 bushels per acre were raised during each of the five years under review.

Oats.—Belgium records an average yield of oats during the five years 1901–1905 of no less than 65 bushels per acre, while Ireland produced 57 bushels and the Netherlands 54 bushels. The smallest average yield per acre recorded is that of Servia, where only 15 bushels were obtained, and European Russia, with 20 bushels.

Corn.—The variations in the average yield per acre of corn are far less marked than the variations in the grains already considered. The almost total absence of its culture from any country included in the northwestern division eliminates the very countries where intensive culture is practiced. The highest yield recorded in 1901–1905 was 22½ bushels per acre in Spain, while the lowest, between 13 and 14 bushels, was obtained in Roumania, Servia, and European Russia.

It is evident from an inspection of all available statistics here cited that the fertility of the older soils of Europe as measured by the yield of cereal crops is fully as great or greater than that of the soils of the United States, and also that the yields have very materially increased during the past century, seemingly much faster than in this country. So far as can be judged from the rather meager records of early days, the yield of cereal crops in the older settled countries of northern Europe at or before the beginning of the last century was not very different from the yields in Russia (still sparsely settled) and in the United States at the present time.

CHEMICAL COMPOSITION OF THE SOILS OF EUROPE AS COMPARED WITH THOSE OF THE UNITED STATES.

It remains now to see if the longer occupation and larger yields of the European countries have materially affected the chemical composition of the soils and sensibly reduced the amount of the mineral plant-food elements. Rocks vary greatly in their ultimate chemical composition, according as one or more of the common minerals predominates, which also gives the essential character to the rock. Soils vary in ultimate chemical composition as the rocks from which they are formed vary and, according to the mode of their formation, are generally more complicated than the rocks with respect to the minerals they contain. It is as difficult, therefore, to compare soils from the chemical composition, unless the type is given, as it would be to compare rocks from the data alone unless the character of the rock were known. As the science of soil classification and soil surveying is new and not on an international basis, it is impossible to compare soils from different countries in any classified or systematic way. The best that can be done, therefore, is to present all the available analyses from a few countries and see if the range in composition is about the same in one as in the others. This method has been followed in the present report, and without attempting to make a selection, and recognizing the unsatisfactory nature of averages with such variable data, all analyses of soil by acid digestion available in the literature in regard to Great Britain, France, Germany, and the United States, in the past eighteen years are given in Appendix B accompanying this report, embracing 1,945 analyses from the United States, 278 from Great Britain, 1,565 from France, and 444 from Germany, or a total of 4,232 analyses.

It must be remembered that the aggregate area of the three countries selected include only a part of the continent of Europe. The total area of Europe is estimated at 3,550,000 square miles, according to Rohrbach, and 3,760,000 according to Wagner-Supan; of continental United States at 2,974,159 (land area) square miles. The area in square miles of the European countries selected for a comparison of the chemical composition of the soil with those of the United States covers only about one-sixth of the continent. The areas, as given in the Statesman's Yearbook, are as follows:

Great Britain and Ireland:		
England	50,848	
Wales	7,467	
Scotland	30,405	
Ireland	32,360	
		121,080
Germany		208,780
France		207,054

The land area in square miles of some of our own States with which these figures might perhaps be compared are:

Texas	262,398
California	156,092
Minnesota	80,858
Missouri	68,727
Illinois	56,002
Alabama	51,279
Florida	54,861
New York	47,654
Pennsylvania	44,832

The method of sampling the soil of a field is not refined, and the chemical methods of determining the small amounts of potash, phosphoric acid, lime, and magnesia in such samples give such variable results, even with the same method on the same sample with the same or with different analysts, that it is unsafe to draw conclusions from slight differences in actual amounts shown even when the differences are proportionally large.[a] It is safer to consider the general range in values for the different localities.

One can not but conclude from the inspection of these data that the chemical composition of the older and longer-used soils of Europe, as regards the principal mineral plant-food elements, is essentially the same as that of the soils of our own country, thus disposing of the fallacious doctrine that soils wear out through loss of plant food by continuous cropping, at least in finite time and to an extent which can be recognized by our methods of observation.

The differences in the chemical composition of the mineral portion of soils as shown by the analyses can not be correlated in general with differences in crop yields; in other words, the fault lies not with the

---

[a] Note the results of the analyses of 73 samples from a field of approximately 250 hectares (617 acres) in St. Viand, France, given in one of the tables in the appendix to this report, where the potash varies from .07 to .51 per cent; phosphoric acid from .03 to .10; and lime from .05 to .47 per cent. Of the 1,565 analyses reported from France there are only 69 cases, and most of these in one canton, where the potash falls below .07 per cent—the minimum found on this field—and 51 cases where it goes above .51 per cent. So that it may be said that the variation in the composition of the soil in this single field, as regards potash, is almost as great as the variation in the soils of France.

For a number of years it has been the practice for the referee on soils of the Association of Official Agricultural Chemists to submit carefully prepared samples of soils to various analysts for analysis according to prescribed instrucmethods of analysis, but rather with the uncertainty regarding the interpretation of such results. There are, in fact, no general significant differences in soil composition as regards the mineral matter, but there are, as we shall see, great and significant differences in the chemical composition of the organic constituents of soils.

An examination of the records of the analyses from 592 localities in the Department of Aisne, France, shows that in 407 cases, or 68 per cent, phosphoric acid is the same or higher in the soil than in the subsoil, and in 278 cases, or 47 per cent, potash is the same or higher in the soil than in the subsoil. The same holds true in general of the soils of this country.

carried in solution and in suspension in our principal rivers and by the wind establishes the fact, as above stated, that loss through normal leaching removes far more mineral plant food than do cultivated crops. In cropping soils, therefore, and removing the crop from the land we remove an inconsiderable amount of mineral material compared with normal losses to which the soil is adjusted through natural laws which are now for the first time being understood.

It seems safe to assume from the foregoing data that the soil (given a sufficiency of water to supply growing plants) is the one indestructible, immutable asset that the nation has. It is the one resource which can not be exhausted—that can not be used up. If the coal and iron give out, the soil can be depended upon to produce food, light, heat, and habitation not only for the present population, but for an enormously larger one. This will become more evident as we discuss the function of the soil as related to crop production. It may be abused and the yield will quickly decline, and it is the large num-

ber of such individual failures that forms the basis for the impression that soils wear out by continuous cropping through loss of plant food. We do not notice so clearly the compensating successes which, as we have seen on the average for the past forty years, have rather more than counterbalanced the failures. To produce its best the soil must be thoroughly understood and properly handled. The proper handling may come from long experience on the same soil, as with the English and German farmers, but even then they have benefited greatly by the scientific work that has been done by individuals and experiment stations. In our own country we have not the general experience gained by long residence on the same land. We have not had the pressing necessity for intensive cultivation, and we have, therefore, more to learn and benefit from a knowledge of the nature of the soil, as we are but beginning to feel the necessity of more intelligent methods, of more intensive agriculture. If our nation can in the present century do what Kellermann asserts the German nation did in the past century, increase the productive capacity of the soils 2½ times, it will be a notable achievement and one well worth the effort. There seems to be no reason why this can not be done. It must be a national effort participated in by all the people, as upon it depends the very foundation of the continued prosperity and integrity of the nation.

THE FUNCTION OF THE SOIL AS A MEDIUM FOR PLANT GROWTH.

The soil is essentially a mixture of a large variety of mineral fragments. Nearly all agricultural lands contain most of the common rock-forming minerals and these minerals contain the mineral plant food elements. These minerals are slightly soluble in water, sufficiently soluble to maintain a solution of about 25 parts per million of potassium and about 8 parts per million of phosphoric acid. This strength of solution is amply sufficient for plants to draw their nourishment from, provided the supply is maintained as the plant withdraws sufficient for its needs. This constant supply is assured by the rapidity with which minerals dissolve—a saturated, although a very dilute solution being obtained after a few minutes contact of the soil and water. The supply, or rather the concentration, is maintained nearly constant by the additional wonderful power the soil has of absorbing mineral matter and the large variety of mineral species, so that the composition and concentration of the soil moisture does not vary greatly for light sands, loams, or heavy clays, nor for what we recognize as productive and unproductive soils.

In 1903 the Bureau of Soils, by very delicate methods, made a large number of analyses of the water-soluble material in fields of growing crops in both good and poor condition to see if any evidence could be found of any temporary exhaustion due to the absorption of mineral matter by the crops more rapidly than the rate of solution, and to ascertain also if constant differences were shown between the productive soils and soils of low productivity. The results, published in Bulletin 22 of this bureau, are restated in Appendix C of this report.

It will be remembered that while the methods of analyses are accurate to within 1 or 2 parts per million, and in the case of potash especially much more accurate than this, on different portions of the same extract of the soil there is sufficient variation in the soil of a field to account for many of the differences shown, especially where the variations appear to be erratic and uneven.

It seems evident from these results and other investigations of the bureau that there is no significant difference in the composition of the soil moisture in good and poor soils, and not even a significant temporary exhaustion of the average soluble mineral content of the soil during the crop season with the crop actually growing in the field. Moreover, the soluble mineral content has generally been found to be as high as or higher in the soil than in the subsoil. Summing up the results of modern investigations, it may be said that soil will not, in general, be worn out or exhausted so far as mineral plant food elements are concerned until most of the minerals of the soils have been dissolved and carried away, which is not conceivable in finite time under natural conditions. It is a fact recognized since the earliest historic times, referred to by many of the old Latin writers and familiar to us all in this country at the present time, that soils differ greatly in productivity and that the productivity of any particular farm or field may decline very markedly and very rapidly. It is no uncommon experience to see a farm, which has been well tilled and kept up to a high state of productivity for many years, rapidly decline when turned over to tenant farmers. Such changes attract the eye in the marked comparison with neighboring crops, dilapidated farm buildings, and general discontent of the less successful man. When the converse of this occurs and these lands are taken up and improved, these differences disappear and the change is less likely to be noted, or, if noted, soon forgotten. It is the same with sickness or disaster to the individual or to the community or to the nation, the years of even success fail to impress the mind as do the seasons of losses and troubles, so that it will come to many as a matter of surprise that on the whole our soils are more productive and that the available plant food supply shows no sign of wearing out. We have, however, a duty to the individual as well as to the nation, especially as in this case where a slight turn from failure to success of many individuals will elevate the nation in its commercial position in the world, so it behooves us to see why it is that many individuals fail to secure from the soil adequate returns, as measured by the returns secured by many other individuals on similar soils, and then to see why one part of our nation secures larger returns of necessary crops than other portions, and to learn if these matters may be equalized.

It is recognized throughout the civilized world that it is better to depend upon proper sanitary conditions to prevent and even to cure most diseases than upon drugs. It is recognized by animal breeders and animal users that sanitation is of the utmost importance; we recognize that fish in our aquarium, that yeast for commercial industries, that bacteria propagated for useful as well as for scientific purposes can only be kept alive and in condition if the products of their own life processes be removed or neutralized from time to time. Our plants are living organisms fixed in position in the soil during life, and like all other living organisms break down as well as build up organic bodies and give off or leave waste products in the soil. Such products appear to be generally harmful to the same species of plant following immediately after a first crop has been removed.

Moreover, this waste matter is further changed by soil organisms, direct oxidation processes, or by plant roots themselves into other degradation products, and finally in our best soils into the material generally harmless to plants which we recognize under the general term of humus. This is probably the complete and ideal form of soil sanitation, but it appears that this change does not proceed normally along such ideal lines in all soils or so as to leave them in their best condition for following crops, and as cultivation and cropping have much to do with these soil changes we are liable, through ill-adapted methods of management, to make matters worse instead of better as time goes on. Intermediate products of plant metabolism are left in the soil in forms, other than humus bodies, which are toxic to plants. Some such organic bodies have been separated from soils by this bureau and found to be toxic to some plants and non-toxic or even stimulating to other plants. Organic bodies of known composition, separated from wheat-sick soils and originated in the soil during the growth of successive crops of wheat, are toxic to wheat plants but not so to cowpeas. Similarly, organic bodies from cowpea-sick soils and formed in the soil during the growth of successive crops of cowpeas are toxic to cowpeas but not so to wheat. After cowpeas have been grown on the wheat-sick soils these bodies, associated with the unfavorable conditions for wheat, are found to have disappeared in whole or in part, and following the cowpeas wheat can again be produced, and so with other crops. Thus we have a logical and demonstrable reason for crop rotation.

Furthermore, lime, nitrate of soda, and certain organic matters such as the green parts of fresh cowpeas, stable manure, and in general organic matters rich in protein material, in decomposing in the soil react on certain of these toxic bodies and change or destroy them, thus improving the soil for subsequent crops. Potash and phosphoric acid appear to act with similar effect, although the action is less well understood. We have here probably one of the principal reasons, and a demonstrable one, for the action of fertilizers and manures in improving the sanitary conditions of the soil.

With this brief statement of the function of the soil as a medium of plant growth, we will turn now to the consideration of the differences in yields of any particular crop on different soils and in various sections of the United States. In the humid portion of the eastern United States, with the same kind of soil material, differing only in texture and water content, the distribution of profitable crops is largely determined by the texture of the soil. On the light sandy members of the series we have conditions favorable to certain fruits and early truck crops. As the texture becomes heavier we find conditions more favorable successively to corn, wheat, and hay grasses. This distribution is typically shown, for example, on the limestone soils of the valley of Virginia. In the Middle West, with a smaller rainfall, we find our best corn soils heavier than the best wheat lands. On the Pacific coast, and in general in the arid and semiarid portion of the country, with and without irrigation, this influence of texture largely disappears.

It appears that this influence of texture is not due to a mere difference in the supply of moisture maintained for the crop, but is due to chemical processes of reduction of the excreta and the remains of plants, which processes are affected both by the amount of moisture in the soil and the temperature.

While it is permissible to judge of the increase or decrease of soil fertility from long-time records of the yield per acre of any crop on the same field or of the same State when the acreage has remained fairly constant, as has been done in the first part of this report, it is not fair to assume that the average yield of about 16 bushels of wheat in New York and about 7 bushels in North Carolina, South Carolina, Georgia, and Alabama, or of about 30 bushels of corn in New York, and 11 or 12 bushels in the latter States, shows that the fertility of the New York soils in general is higher than the fertility of the other States, for, measured in other crops, the reverse might be shown. The figures do show, however, that so far as grain production is concerned the soil conditions in New York are more favorable than those of the South. This does not appear to be so much the effect of climate on the plant as of the plant's effect on the soil, as may be shown in a variety of ways. The same difference in yield of the cereal crops is shown in the countries of the north and south of Europe as in our own northern and southern States.

The largest yield of corn per acre on record (209 bushels) was on a trial acre in South Carolina, where the average yield is but 9.7 bushels, and very large yields are reported where a new method of culture is being tried of checking the vegetative growth with the toxic effect of weeds in their early stages of growth, followed by thorough cultivation and judicious fertilization.

The subsoil is generally toxic to crops in the humid southern States, but is as a rule equally as productive as the top soil under the arid climate of the West. There is every reason to believe that other varieties of our grain crops may be originated through selection which will be better adapted to southern soil conditions than those we now have, or that methods of culture may be devised which will permit of a much larger yield of grain in the Southern States than we now obtain.

One of the most interesting cases which appears to show the influence of the climate on the soil as a medium of plant growth is the case of the alfalfa crop. Adapted to almost all types of soil west of the Mississippi River under moisture conditions suitable to other crops, it has almost universally failed in the soils of the humid Eastern and Southern States, with two notable exceptions. One of these is the Dunkirk stony loam of New York, and the other the Houston clay extending from Alabama to Texas. The failure in the East is not due to lack of plant food. Inoculating the soil with the specific alfalfa bacteria does not insure success, nor can failure be attributed to the influence of climate on the crop, as there is no greater range of climate in the East than in northern New York and southern Alabama where the plant grows successfully on two different types of soil.

The following interesting article appeared in a recent number of "The Southern Planter:"

> Alfalfa is undoubtedly a splendid forage plant where it will thrive without undue attention from man; it may be said to be the backbone of far western agriculture; but, like many other promising field crops, it should be studied with reference to soil and locality before extensive planting. A great many eastern farmers have failed ignominiously with alfalfa, and on a large scale, when a little less enthusiasm and a little more careful testing would have been the part of wisdom.

"West of the one hundredth meridian," said Professor Spillman, the agriculturist in charge of Farm Management, of the Department of Agriculture, in answer to the inquiry as to the department's present knowledge of alfalfa, "character of soil is but little considered in growing alfalfa; it will thrive anywhere that there is water. East of that line the plant is very discriminating as to its food. Wide experiments have been made by the various experiment stations and the Department of Agriculture all over the East, and in only a few circumscribed localities does it 'grow as a weed.' In some sections of the South, in a small limestone region of New York and southern Vermont, and in a few other scattered localities it grows readily, while it also does very well in parts of Wisconsin, Minnesota, and Illinois. But thousands of alfalfa fields in all the Eastern States have failed, and, while it is now known that alfalfa can be grown on these fields, the cost is, in the majority of soils, prohibitive.

"* * * It should not be expected that in the East the plant will endure and thrive twenty or thirty years as it does in the West," continued Professor Spillman. "If it would, the first cost of securing a good stand, however great, would be an inconsiderable quantity; but even where a good stand is secured the usual life of the field is, on lighter soils, one or two years, ranging up to five years on heavy, rich soils, with as high as three cuts per year, except in the specially adapted localities above mentionel."

It is an interesting fact developed by the Soil Survey that two soil types extending through different climatic regions best adapted respectively to corn and wheat in one locality will show the reverse adaptation under different climatic conditions. In the progress of the Soil Survey, the bureau has mapped 122 types of loam soils in the United States. About 58 per cent of the total acreage of these soils should be given first rank in the production of some one or more of our staple crops, about 26 per cent medium rank, and about 16 per cent low rank. They all have approximately the same texture, although they differ in the character of the soil material, mode of formation or deposition, and may differ in structure. They certainly differ in their relation to crops, or require different methods of management to produce crops. So far as investigations have gone, they all would seem to have an adequate supply of mineral plant food elements in the soil moisture, yet they appear to have dissimilar chemical powers, especially as regards the reduction of organic bodies, and the products of the same. Considerable progress has been made in selecting new crops and special varieties of crops for some of these soils, and important special industries are already established on soils which a few years ago had low agricultural rank. There seems to be great possibility in this direction in the future.

METHODS OF CONTROL.

Certain plants adapt themselves to certain soil conditions and grow for long periods in an undisturbed soil. This is true generally of forest growths and of most native vegetation. The buffalo grass is fast disappearing with the advent of the plow. The huckleberry bush has not been successfully cultivated until recently, when done through root fungi. Many plants do well in association with certain other plants and will not grow at all in other associations. Practically all of our annual crops, however, require cultivation always before and many of them during most of their periods of growth. This cultivation loosens the soil and puts it in better physical condition for the crop to start in, tends to conserve the moisture, and to keep out weeds, which are generally undesirable by reason of the toxic action of the organic matter thrown off by their roots. But cultivation does more than this. Plowing is essentially a method of fermentation, or, rather, a method to regulate fermentation in the soil; as aromatic principles are developed in certain tobaccos by properly regulating the supply of air by occasionally opening the bulk, so the soil is relieved of many objectionable organic bodies by proper cultivation and the judicious introduction of air. The color of an infertile soil or a raw unproductive subsoil recently turned up to the surface will gradually change and generally darkens with thorough cultivation, and the change in color will indicate to an experienced eye the progress toward more productive conditions.

This is the oldest as it is still the most fundamental method of control of soil fertility. It is a method, furthermore, which requires a high degree of judgment and of skill. Each class of soil requires its own peculiar method, and each change of climatic condition must be considered.

It is often as injurious to plow too much as to plow too little. The time, manner, and condition of the soil are all important factors in regulating cultivation for the maintenance or improvement of fertility. The American farmer has much to learn regarding the best method for the mere handling of his soil. Much of this must come from hard actual experience on the same type of soil for a period of years, but much help may be rendered him through the elucidation of the many at present obscure changes involved in the proper sanitation of the soil.

The second method of controlling the fertility of the soil, and one almost as old as cultivation, is the proper rotation of crops, the importance of which was recognized by the old Latin writers, and clearly recognized by the early English writers.[a]

As soon as we remove the native vegetation which has become adjusted to the soil and introduce new crops forced under cultivation to produce the largest possible yield, the capacity of the soil to reduce

---

[a] According to A. B. Griffith, the earliest English work of importance on agriculture was "Ye Boke of Husbandrie," by Sir Anthony Fizherbert, published in 1534. Twenty-eight years after the publication of Fitzherbert's work, Martin Tusser published his famous "Five Hundred Points of Husbandrie" in which he strongly recommends the rotation of crops, thus:

"Otes, rie or else barlie, and wheat that is gray,
Brings land out of comfort, and soon to decay;
One after another, no comfort betweene
Is crop upon crop, as will quickly be seene,
Still crop upon crop many farmers do take,
And reape little profit for greedinesse sake."

A Treatise on Manure, 3rd edition, page 3 (1903).

With all the development of modern agriculture in the taking up of new lands and the enormous increase in the aggregate crop production of the world, it seems apparent from the old writers that agriculture as an art has declined.

According to Dickson, the Romans had a greater variety of crops and exercised considerable more care in adapting them to the different soils than did the English at the time he wrote (1788) or more than we seem to give in this country. Considering Pliny as more particular in his directions as to the adaptation of crops to soil, Dickson gives Pliny's maxims in detail as follows:

"'Such a difference of soil,' as Pliny says, 'points out the necessity of describing the kinds proper for the different crops. This is Cato's opinion, that corn should be sowen on land that is stiff, rich, and in good heart; that raddish, the organic excreta and maintain proper sanitary conditions is often taxed beyond its power to maintain the yield, especially if the same crop is grown year after year. When the crop is changed, a certain crop appearing only once in three or four years, the soil has a longer time to dispose of the waste products. There are, however, two other principles underlying the practice of rotation which, if intelligently used, make it a highly efficient method of control of soil fertility. Some plants are quite indifferent to and are even stimulated or at least benefited by the excreta of other plants, and in thus benefiting they aid in destroying the toxic organic bodies and in purifying the soil.

By growing successive crops of cowpeas or of wheat in small volumes of soil, the bureau has succeeded in making this soil sick for either crop respectively. Pure organic bodies have been isolated from both the soils which are toxic to the plants producing them, but beneficial to the plant which has not caused their accumulation. When wheat is produced on the cowpea soil, therefore, it usually grows better, and after the wheat, cowpeas will grow again better than before. This, in brief, is the principle of rotation modified in details by the nature and previous cropping of the soil and by climatic conditions. The application of empirical rules brought down to us through long experience is very beneficial in maintaining fertility, but much may be expected from the investigation now going on, which will make the practice more effective and more reliable.

The third method of control, namely, the use of manures and commercial fertilizers, has likewise long been practiced, but within recent years the use of commercial fertilizers has grown to enormous proportions in some sections of the country, although used very little or not at all in other sections. The present practice of fertilization is based upon the fallacious doctrine that the soils become exhausted of plant food through continuous cropping and gradually become worn out. If this were so it would have the population of the world eventually dependent upon a few comparatively small deposits of nitrates,

---

millett, and panic, should be sowen upon the same kind of land, if moist or wet; that seed should be first sowen in cold and wet, soils, and afterwards in warm; that lupines should be sowen in the red soil, the soil called pulla or sandy soil, if they are not wet; *far* in moisture fields, where the soil is chalky and red; *triticum* [wheat] in dry land, not liable to weeds, nor in a shade; beans in strong soils; *filigo* and *triticum* in open and exposed fields, that receive greatest benefit from the heat of the sun; lentils in uncultivated and red soil where there is not much grass; barley on fallow, and land so rich as to carry a crop every year. Spring sowing should be used in places that cannot conveniently be sowen in autumn, and in soils whose fatness can carry constant crops: This maxim too is exact. These things should be sowen in shallow soil, that do not require much sap, as the *cytifus* and *cicer;* legums are excepted, which are pulled up and not cut in reaping; hence they are called legums, because thus gathered. In fat soil should be sowen such things as require much food, as garden erbs, *triticum*, *filigo*, flax. So for the same reason, the shallow soil is allotted for barley, because it does not require much food, the richer and stiffer for triticum. In low lying grounds, *far*, rather than *triticum*, should be sowen. In grounds neither very high or low, both *triticum* and barley; hilly ground produces plumper triticum, but not so large a crop: Far and filigo may be appointed to chalky and wet soils.' "

Theophrastus does not enter into particulars, as the Roman authors do, but he declares, in general, that to know how to adapt plants to soils is one of the principal things in agriculture.

The Husbandry of the Ancients; Adam Dickson, Edenburg, 1788; page 187.

phosphates, and potash, and the regulation and conservation of these deposits would be of far more importance than of the coal and iron supply. But we have seen from the statistics given that the soils of the world are not wearing out, but, on the whole, are becoming more productive, and that even the more unproductive soils have ample supplies of mineral plant-food constituents in their soil moisture for better crops than they produce.

While plants may, and undoubtedly do, avail themselves of the mineral plant food elements of the manures and fertilizers, it appears from modern investigations, and is entirely in harmony with experience, that this is not the only benefit derived from their application. Toxic organic bodies which the soil finds difficult to reduce are frequently much more quickly and effectively reduced in the presence of an easily decomposible substance, like fresh cowpea vines or properly fermented manure, while nitrates and other mineral salts help to oxidize or otherwise change to harmless forms the toxic material, thus assisting in the proper sanitation of the soil. Furthermore, certain plants and fertilizers together are much more effective in destroying these toxic bodies than either alone, so that in the rotation for any particular soil there is an order in which the plants should succeed each other, and also when manures and fertilizers are used a most efficient place in the rotation when these should be used, as has already been determined empirically from experience. The effect of cultivation, crop rotation, and fertilizers in improving the physical condition of the soil need not be dwelt upon here.

CONCLUSION.

The fertility of the soil is a great national asset which can not be exhausted. It is not being developed or availed of in all cases as it should be, and will not be until, through investigation, we know more of the peculiarities of certain of our soils, their adaptation to crops, and special methods of control. The soils in different sections of the country are unequally adapted to certain of our staple crops, which permits of specialization, or this difference can undoubtedly be largely minimized through new and improved methods of control if desirable.

In all sections, as in all business and professional work, we have individual cases of failure and success, the cases of failure being generally due to inefficient methods and lack of knowledge, which can be overcome only by better training and education. On the whole, the management of the soils of the world seems to be improving, at least in modern times. This improvement appears to have been greater in Europe, where the population has been denser and the need more pressing than in our own country.

The time has now arrived, when practically all available new lands in this country have been taken up, when improvement must be more rapid than in the past to maintain the integrity of the nation and its commercial supremacy among the nations of the world, and this can best be done by continuing and extending the educational work and the investigations along broad national lines which the administration and the Congress have supported in the past.

APPENDIX A.

Acreage and yield per acre of cereal crops in European countries.

---

[a] Winchester bushels.

[b] Area returned by the census of 1901 as intended for the crop named at the time of fall planting; the area actually harvested in 1901, owing to the failure of the wheat crop, differed considerably from these figures.

APPENDIX B.

Chemical composition of the soils of the United States, Great Britain and Ireland, France, and Germany, with respect to potash, phosphoric acid, lime, and magnesia.

CHEMICAL COMPOSITION OF THE SOILS OF THE UNITED STATES.

State or Territory.	Original sample No.	Potash (K_2O).	Phosphoric acid (P_2O_5).	Lime (CaO).	Magnesia (MgO).
		Per cent.	*Per cent.*	*Per cent.*	*Per cent.*
California [a]	1	0.555	0.230	0.955	1.052
Illinois	3	.161	.066	.210	.247
	5	.525	.106	.610	.643
Kansas	7	.643	.089	.575	.510
Indiana	9	.496	.166	.465	.450
Massachusetts	12	.153	.144	.525	.558

COMMERCIAL FERTILIZERS AND FERTILIZER INSPECTION.

By Dr. MILTON WHITNEY,
Chief of Bureau of Soils, United States Department of Agriculture.

It has been shown in the discussion of "Crop Yields and Soil Composition" that there are three principal methods of control of soil fertility, a subject which is the very foundation of the material wealth of this nation and of its position among the countries of the world; these are cultivation, rotation of crops, and fertilization. Of these, the first two are in the hands of the farmer himself, and require only knowledge, intelligence, and skill in manipulation. Fertilizing materials, however, have, to a very large extent, to be gathered for him from different parts of the world and manipulated before they are ready to be applied to the land.

It was early found that unscrupulous manufacturers were ready to, and actually did, perpetrate gross frauds upon the farmers by selling worthless material for exorbitant prices.[a] The first practical method devised to meet the situation in this country was a voluntary agreement or understanding between the manufacturers, dealers, and farmers, to submit for analysis samples of all brands offered for sale or purchased in a State to some competent chemist in the agricultural society, state department of agriculture, or experiment station, as a final arbiter. Such an agreement was entered into in Connecticut in 1876, and the reasons for it and terms of agreement are given in an appendix of this article.[b] Subsequent to this, most of the States passed very strict and comprehensive fertilizer-control laws, which have worked admirably in preventing frauds, to the advantage alike of manufacturers and farmers. Broadly speaking, this regulation has been vested in the state experiment stations in the Northern States and in the state departments of agriculture in the Southern States, and is based upon the general policy of police regulations for the public good. Generally speaking, also, a fee is exacted from the manufacturers in the Northern States, based upon the number of valuable plant-food constituents (phosphoric acid, nitrogen, and potash) claimed to be present in the fertilizers, while in the Southern States, besides a fee for registration of brands, a tax of so much per ton is exacted, thus providing a considerable revenue for the State.

---

[a] See transactions of the Connecticut State Agricultural Society for the year 1859, p. 41.

[b] Previous to this, however, the State passed a law making it mandatory for all manufacturers or dealers to affix a guaranteed analysis to each package of fertilizer, with certain exceptions, and authorizing the president of the State Agricultural Society to have analyses made at his discretion, and prosecute for frauds, under his judgment.

On account of the interstate character of the fertilizer trade, it has not been possible for the state authorities to maintain a factory inspection, and they have had to rely upon the guaranty of the manufacturer as to the nature of the material which has been put into the fertilizer (which statement is generally considered confidential), and upon their own analysis of samples picked up at random in the open market. This has, from the first, been recognized as a weak point in the present fertilizer-control system. The analysis is recognized as merely a commercial valuation, with little or no connection with the agricultural values of the fertilizer.

At first the inspecting officers determined merely the total amount of nitrogen, the water soluble potash, and the water and citric acid soluble phosphoric acid, and allowed a liberal value for each of these ingredients when contained in a mixture, based upon the assumption that only high-grade goods had been used by the manufacturer. The tendency in quite recent years, however, is for the inspecting officers to make more complete analyses, in an effort to show more about the origin of the materials in the mixtures. It is obviously impossible from any analysis, however complete, or from any microscopical investigation to determine with accuracy the character of the material that has been used, and the only method by which such information could be reliably placed before the purchasers would be by factory inspection, in which the kind and amount of material used in the mixture would be certified on the package and vouched for by the impartial inspector.

The reason for the beneficial effects of fertilizers has long been held[a] to be due to the supply of mineral plant food to the soil in a more soluble or available form than is found in soils of low productivity. That this is not the most important function of fertilizers has long been suspected by thoughtful men, who could not reconcile many well-known and obvious facts with this plant-food theory. Nevertheless, it was not until the investigations of the Bureau of Soils into the chemistry of the mineral portion of the soil, showing the remarkable constancy of composition of the soil moisture and demonstrating the reasons for this, that we were able to say conclusively that this is not the chief nor most important function of fertilizers. Not until the researches on the chemistry on organic matter in the soil had revealed the presence of toxic organic bodies, resulting from the growth of crops, and the analogy was seen with the metabolic processes of the animal body, and the processes for the elimination of the waste products so formed, did rational reasons for cultivation, crop rotation, and fertilizers become apparent, among others being the elimination of harmful waste products and the preservation of proper sanitary conditions in the soil. It was then evident also why the ordinary chemical analysis of the soil had failed to reveal the fertilizer requirements, and why different substances, having the same chemical ingredients, often have very different effects on soils and crops.

---

[a] The use of commercial fertilizers is not old. The first lot of natural guano was imported into England in 1840, and nitrate of soda about 1830. The potash deposits of Germany were first worked in 1862. The phosphate deposits in South Carolina in 1868. Phosphates were discovered in Florida in 1888, and in Tennessee in 1894.

A great fertilizer trade, estimated at from $80,000,000 to $100,000,000, or approximately 1 per cent of the total value of our agricultural products, has been built up on the supposition that soils wear out and become exhausted of their available mineral food, and that it is necessary, in order to maintain the fertility of our soils, to bring nitrates from Chile, potash from Germany, and phosphates from certain deposits in this country in order to return to the soil the equivalent of what is removed by our crops.

That it is the material and not the element which determines the possible agricultural value of the fertilizer is becoming more and more evident every day. Most of the States prohibit the incorporation into commercial fertilizers of such substances as ground leather, horn shavings, feathers, hair, wool waste, or muck, although these are highly nitrogenous, because it is the general belief that they are ineffective when applied to the soil. It is not believed by competent persons that nitrate of soda, sulphate of ammonia, and the various organic forms of nitrogen commonly used in fertilizers are equally effective on all soils, crops, and in all seasons. Indeed, we have undoubted evidence that they may differ widely, and yet we apply them indiscriminately and without certain knowledge of what we are using in our commercial fertilizers. The same way with the materials furnishing phosphoric acid and, to a less extent, with potash. It is true that the inspecting officers of the various States are making more complete analyses in order to determine more nearly the nature of the materials in the mixture, to verify the statement of the manufacturers, but it is admitted that this is only approximate and incomplete. There is nothing accomplished by the present system of inspection which the factory inspection would not show much better, besides giving the certain information that we are purchasing nitrogen in the form of nitrate of soda, sulphate of ammonia, cotton-seed meal, tankage, and other forms, which information may be the means of insuring success and of establishing a rational system of fertilization which up to this time has not prevailed in this country. In the nature of the case the States can not maintain a general factory inspection, but the Federal Government can, as they do in meat inspection.[a] The chief objection to federal inspection has been that it would remove certain sources of revenue from the States, but there seems no valid reason why even with federal inspection the States can not still exact a fee from dealers and a tonnage tax on the amount sold in the State.

It has been stated above that there is no rational system of fertilization in general use in this country, and in this respect the United States appears to be far behind some European countries. We have, indeed, a general idea of the form of fertilizer material adapted to some of our soils and crops and some idea of the relation of soil conditions and climatic conditions to fertilizer action, but these ideas are not based upon exact facts and are not practically applied by our fertilizer manufacturers or farmers.

---

[a] The Twelfth Census gives 422 fertilizer manufacturers in the United States.

The advice of our agricultural chemists and agronomists is almost universal that farmers should test their soils by plot experiments to determine the most efficient forms and combinations of fertilizers. Such experiments are costly and take time, and results vary with different seasons. Such of our experiment stations as have carried on these fertilizer tests hesitate to draw conclusions with less than an average of ten years. One of the most recent of the standard books on fertilizers[a] asserts in the most cautious way and with many qualifications that corn is particularly responsive to phosphates, cereal crops to nitrates, grasses and clovers to phosphoric acid and potash, beets and carrots to nitrogen, potatoes and sweet potatoes to potash, and truck crops to nitrogen, and yet with only this meager information, not pretending to be exact or invariable, we find a multitude of brands on the market, many of them being prepared and recommended for special crops. One has but to look up the reports of the departments of agriculture and state experiment stations charged with the inspection of fertilizer materials to see the absolute lack of system which prevails in the fertilizer trade. The tendency in this country seems to be to increase the number of special brands for special crops, but there is an absolute lack of uniformity, even in the elementary composition of these special brands.

As a rule, the fertilizer formulæ are simpler and more uniform in the South than in the North, and there are also a less number of special brands for special crops. For example, there are very few fertilizers for special crops offered in the States of Alabama and Georgia. In North Carolina about 28 per cent of the whole number of brands of fertilizers sold in the State are recommended for special crops. In Connecticut 45 per cent of the whole number of brands sold are special brands for special crops. In the State of Georgia there were 1,822 brands inspected, analyzed, and placed upon the market for sale in 1908. Of these, 1,260 brands contained two or more of the plant-food elements (phosphoric acid and nitrogen or potash) in 106 different combinations, as shown on the guaranties; 1,143 of these brands, or 90 per cent, contained 6 or more identical guaranties covered by 26 combinations; there were 255 brands, or 27 per cent, of the complete fertilizers which contained 10 per cent of phosphoric acid, 2 per cent of ammonia, and 2 per cent of potash. There were 242 brands, or 26 per cent, which contained 8 per cent of phosphoric acid, 2 per cent of ammonia, and 2 per cent of potash. If these brands differ in the material of which they are composed, the farmers should know it to enable them to make a more intelligent selection for their particular soils and crops, but there is no way in which they can find out whether the brands differ or not. It is also to the interest of the manufacturer to have this known. The brands undoubtedly differ in effectiveness by reason of the materials which they contain, and we are sadly neglecting our opportunities of developing agricultural practice by failure to know the material these fertilizers actually contain. Of the 33 special brands for tobacco placed on sale in the State of Connecticut, phosphoric acid ranges from 3 to 9 per cent, ammonia from 2 to 7¼ per cent, and potash from

---

[a] Fertilizers, by Edward B. Voorhees, 1902.

2 to 11 per cent; there are 24 different combinations in the 33 brands issued for this very limited crop in Connecticut. Instances of this kind could be multiplied almost indefinitely, and it is considered best to submit with this report an appendix giving a very complete analysis of the figures relating to the fertilizers on sale in three of the Southern States (Alabama, Georgia, and North Carolina) where the fertilizer control is under the state departments of agriculture, and in three of the Northern States (Maine, Massachusetts, and Connecticut) where the fertilizer control is vested in the state experiment stations.

Most of the States regulate by law, or by executive order under authority of law, material which may or may not be used in commercial fertilizers and the words which may be printed or stamped on the brands. Thus the State of Georgia prohibits the use of the word "standard" in connection with a brand containing less than the commercial equivalent of 8 per cent of phosphoric acid, 2 per cent of ammonia, and 2 per cent of potash; and of the words "high grade" on any fertilizer containing less than the commercial equivalent of 10 per cent phosphoric acid, 2 per cent ammonia, and 2 per cent potash, although both of these combinations are far below the combinations recommended by the state department of agriculture for crops.

It is the general belief at the present time that a fertilizer for tobacco should be rich in potash, and that for cigar tobacco the potash should be in the form of carbonate, yet we find in Connecticut special brands for tobacco with from 1 to 3 per cent of potash, and so far as the evidence permits one to judge the potash in the majority of brands is not in the form of carbonate. It would seem that it would be possible by law, and a protection to the farmers, to prohibit the use of the word "tobacco" on a brand of fertilizer containing less than 6 per cent of potash, to be contained in the form of carbonate only.

It is the general belief that potatoes require fertilizers rich in potash, and that it is better to have the potash in the form of sulphate, yet we find brands of special fertilizers for potatoes offered for sale in Maine with only 2 and 3 per cent of this ingredient. In this case also it should be possible under the law, and a protection to the farmers, to prohibit the use of the word "potatoes" on any special brand for potatoes with less than a minimum of, say, 6 per cent of potash, and this in the form of sulphate only.

It is believed and taught by the Maine Experiment Station[a] that nitrogen for potatoes should be in the form of nitrate nitrogen, and yet even in that State the principle is not enforced by law, and the nitrogen supply in special fertilizer brands for potatoes is of such form as may be determined by the manufacturer. It is the general belief that sugar beets require a fertilizer rich in potash, and that it is best to have this in the form of chloride or muriate; but no particular attention seems to be paid to this in the preparation of special brands, and farmers do not know what materials they are purchasing, and can not know with the best system of inspection which is being maintained by any State.

Instances could be multiplied indefinitely where our practice does not conform even to our present best knowledge.

---

[a] Bul. 153, Maine Agr. Expt. Sta., March, 1908, p. 105.

The only conclusions that can be arrived at from the study of this material are—

That the form of inspection that has prevailed in the past is inadequate for the growing needs of the farmer for more definite and more explicit information in regard to the composition of the materials going into the commercial fertilizers, and that proper inspection can only be made by the Federal Government on account of the interstate character of the fertilizer trade.

That there is no rational system of fertilization in this country, and although we have an enormous trade in fertilizing material, it is absolutely necessary that the whole question of the effective composition of fertilizers be investigated in order to work out the most effective and most efficient system of fertilization.

And that our knowledge of the requirements of special fertilizers for special soils and crops is wholly inadequate to the needs of our people, and the subject requires a thorough and complete investigation in order that we may use our valuable fertilizing materials to the best advantage, making this method of the control of soil fertility of the higest efficiency. The time has come when we begin to know something of the true principles of fertilizer action and when the methods of investigation are adequate to solve this very intricate problem, which has grown to enormous proportions upon no adequate knowledge or basic efforts to insure the success which we should reasonably expect.

APPENDIX A.

EXTRACTS FROM OFFICIAL REPORTS AND STANDARD BOOKS ON FERTILIZERS.

The following extracts do not pretend to be a complete résumé of the literature on fertilizers, as the subject is very voluminous, but only to give a few striking statements from recognized authorities on the points which have been made in the preceding report:

In its work in connection with commercial fertilizers, in detecting and driving out frauds, placing the trade on a rational basis, encouraging honest manufacturers and sellers, and teaching farmers how to select their fertilizers wisely and use them with profit, its [the experiment station's] usefulness can not be overestimated. (First Annual Report, Conn. Agr. Expt. Sta., 1876, prefatory note, p. 3.)

The means adopted by the station to regulate the sale of fertilizers in the State has been explained quite fully in Circular No. 4 of the station. * * * The plan is substantially the same as has, with various modifications of detail, come into quite general usage in Germany and other European countries. The essential features are:

First. An agreement made with the station by dealers in fertilizers to sell their wares by guaranteed analysis, the verification of the analysis being left to the station; and

Second. A provision whereby purchasers may have samples of the articles they buy analyzed by the station at small cost or for nothing.

In order to preclude all chance for mistake or cavil as to the precise terms of the arrangement referred to a form of agreement has been signed by the dealers who desired to place their wares, as sold in the State, under the supervision of the station.

The form referred to is the result of deliberations of a large meeting of manufacturers, sellers, and consumers of fertilizers held at the station and of consultation with the advisory committee and with other parties interested. It is as follows:

BLANK B.

------ hereby agree with the Connecticut Agricultural Experiment Station, as represented by its directors, that all fertilizers offered for sale in the State of Connecticut by ------ or by ------ authorized agents, at any price above $15 per ton, except crude fish scrap, shall be placed under its supervision in the following manner:

1. ------ hereby agree that all fertilizers above described shall be guaranteed to contain certain minimum percentages of one or more of the following ingredients:

   Nitrogen.
   Phosphoric acid; soluble.
   Phosphoric acid; reverted.
   Phosphoric acid; insoluble.
   Potash.
   Sulphuric acid; chlorine.

2. ------ also agree that the above guarantee shall be always subject to verification by analyses made at the stations.

3. ------ also agree that all fertilizers above described shall be at all times open to the inspection of the station, as represented by its director, chemists, or any member of its advisory committee. * * *

The signer of this agreement is not expected to specify in this blank the composition of the wares he sells, but he does bind himself to fulfill the requirements of the state law, by accompanying every package of fertilizer sold with a plain statement of the analysis, using the above terms, and to guarantee the article to be equal to the analysis.

In brief, this statement binds the signer simply to state what he sells and guarantees what he states, the verification of the statement being left to the official analysis of the station. With the fulfillment of this guarantee the responsibility of the seller will naturally end. The station provides that buyers who wish to determine whether the articles they purchase are equal to the guarantee, may have control analyses made at little or no expense. It is believed that no simpler nor more efficient way can be devised to place the trade in fertilizers on a more secure basis, insure confidence, and benefit all concerned. (First Annual Report, Conn. Agr. Expt. Sta., 1876, pp. 14–16.)

The question as to which is the most serviceable and best fertilizer is like the question, Which is the best and most serviceable medicine?—impossible to answer. All depends on the patient, on what ails him, and on how he is being treated otherwise.

The experiment station might be compared to a sanitary engineer, but not to a practicing physician. We are unable to prescribe for land. The only way is for the practical farmer to make trials on his land with fertilizers or fertilizing chemicals which he knows are of good quantity (quality?) and study the effects. * * *

There is a choice also in respect to action on the crop. This will depend somewhat on the character of your soil and can only be learned by experience. One fertilizer will appear to be best one year or on some crops and land, and another season, owing to the different weather, wet or drought, or on other land or plants another kind of fertilizer will give the best results. I should try a fertilizer that would give me a good percentage of nitrogen, soluble phosphoric acid and potash, for the least money.

We can give no formula for an onion manure. The food which the onion requires is the same that all other crops require. If it requires any special proportions of fertilizing ingredients, neither we nor anyone else can positively say what that is. Probably a fertilizer having about the composition of the "special" onion, potato, tobacco, or corn manures would be as profitable a fertilizer as you could apply to the onion. * * *

It is a fact of common farm experience that nitrogenous manures differ widely in their efficiency. Nitrate of soda, for example, often has a visible effect on grass land within ten days after sowing; dried blood requires a longer time to affect the color or growth of grass, while an application of leather or hair may never show the slightest effect. * * *

A considerable number of manufacturing wastes, rich in nitrogen, but differing greatly in their values as plant foods, are now on the market, and their use is urged upon manufacturers of mixed fertilizers. In general, such of these waste products as are agriculturally of least value are also least expensive, and therefore the temptation to use them in manufactured goods is to some very strong.

It is highly desirable to know in the first place how these nitrogenous wastes compare with each other, and with some standard, such as nitrate of soda in availability and various experiments have already accomplished something in this direction. In the next place it is important, either to be able to identify these various "ammoniates" and mixed fertilizers or else to have some means of distinguishing in such fertilizers between available and inert nitrogen; some measure of its availability. Unfortunately it has hitherto been difficult or impossible to identify with certainty most of the inferior ammoniates, either by inspection or by ordinary chemical tests. The treatment with acid during the process of manufacture, the grinding, and the mixture with phosphatic material and potash salts so alters the structure and appearance that in many cases the microscope fails to identify anything and chemical tests are not generally applicable. (Annual Report Conn. Agr. Expt. Sta., 1885, pp. 110–115.)

We have reason to believe from extended observations and experience in the field that hundreds of thousands of dollars are annually wasted by farmers in the lavish and injudicious application of fertilizers on cotton. The author shows that the different forms of phosphates and the different materials used to supply nitrates vary greatly in their efficiency. (Fertilizers for Cotton, J. M. McBryde, Farmers' Bulletin 14, 1894, p. 7.)

"The most satisfactory, and, indeed, usually the only method," says Armsby, "by which we can at present determine the needs of a soil is to ask the question of the soil itself by growing a crop upon it with different kinds of fertilizers and noting the result. Such soil tests with fertilizers have in many cases given results of which immediate practical value for the locality in which they were undertaken."

Many materials containing the essential elements are practically worthless as sources of plant food because the form it not right. * * * All materials containing organic nitrogen are valuable in proportion to their rapidity of decay or change. * * * Thus organic nitrogen differs in availability not only according to the kind of material which supplied it, but upon the treatment it receives. * * * The phosphoric acid in natural or untreated phosphates is insoluble in water and not readily available to plants; that is, the rate of availability depends largely upon the rapidity with which the substance rots or decays, and the rate of decay again depends upon the character of the substance with which the phosphate is associated. * * * Potash may exist in a number of forms, though chiefly as chlorids, or muriates, in which case the potash is combined with chlorin; and as sulphates, in which the potash is combined with sulphuric acid. With potash, however, the form does not exert so great an influence upon availibility as is the case with nitrogen and phosphoric acid. All forms are freely soluble in water, and are believed to be nearly if not quite equally available as food. The form of potash has, however, an important influence upon the quality of certain crops, due rather to the constituents with which the potash is associated than to the potash itself. * * * The character or form of the material used must therefore be carefully considered in the use of manure. * * * All manufacturered products or brands of fertilizers are made up of a mixture of the various kinds and forms of fertilizing materials just described, and the differences that exist in the brands of different manufacturers are due both to differences in the character and to the variations in proportions of the materials used to form the different brands; that is, while all manufacturers must go to the sources of supply indicated, they may select either good or poor products and may vary the proportions of the different materials used.

The difference between a good brand of fertilizer and a poor one lies not so much in differences that may exist in the total amount of plant food contained in it as in the quality of the materials of which it is made. (Commercial Fertilizers, Farmers' Bulletin 44, Edward B. Voorhees, 1896.)

The following extracts are from Fertilizers, by Edward B. Voorhees, originally published in 1898, with a fourth edition in 1902:

Preface: There is no question as to the desirability of the use of commercial fertilizers on most farms, though the methods now generally practiced are such as to indicate the very great need of a better understanding of what the functions of a fertilizer are, of the terms used to express their composition and value, of the kind that shall be used, and the time and method of application for the different crops under the varying conditions that exist. * * * The author appreciates keenly his limitations, owing to the lack of definite knowledge on many vital points; yet it seems that at this time, when the investigations of the experiment stations are beginning to be regarded as important educational factors, and when these institutions are more than ever prepared to study the fundamental principles which underlie the various processes involved in plant nutrition, the practical man should have a clear understanding of what is now known, in order that he may be prepared to accept and use that better knowledge which will undoubtedly be provided for him in the near future.

Page 49: It will be observed from the foregoing brief description of the chief sources of organic forms of nitrogen that a very wide variation occurs both in the composition or content of nitrogen in these products and in the availability of their nitrogen, or rapidity with which, under similar conditions, it is given up to plants. The fact that a substance contains nitrogen in considerable amounts and in an organic form, then, is not a sufficient guide as to its usefulness.

Pages 54–57: The practical point, and the one of prime importance to the farmer, is, then, to know how to estimate the relative value or usefulness of these different products, what is the rate of availibility as compared with nitrate, and thus the relative advantage of purchasing the one or the other at the ruling market prices. Relative values, however, can not be assigned as yet, though careful studies of the problem have been made, chiefly by what are known as "vegetation tests," that is, tests which show the actual amounts of nitrogen that plants can obtain from nitrogenous products of different kinds when they are grown under known and controlled conditions. The results so far obtained, while only serving as a guide, indicate that when nitrate is rated at 100 per cent, blood and cotton-seed meal are about 70 per cent, dried and ground fish and hoof meal 65 per cent, bone and tankage 60 per cent, and leather, ground horn, and wool waste range from as low as 2 per cent to as high as 30 per cent. These figures furnish a fair basis for comparing the different materials when used for the same purpose or under the same conditions. If, for example, the increased yield of oats due to the application of nitrate of soda is 1,000 pounds, the yield from blood and cotton-seed meal would be 700 pounds, the yield from dried ground fish and hoof meal would be 650 pounds, from bone and tankage 600 pounds, and from leather, ground horn, and wool waste, from 20 to 300 pounds.

These figures alone are, however, not a sufficient guide as to the kinds to buy under all conditions, since the usefulness of the different forms are again dependent upon such other conditions as the kind of crop, the season, and the object of the application. * * * In the making up of fertilizers, all of these considerations should be carefully balanced, and it is the practice on the part of many manufacturers to use a part of each of the three forms, so that a continuous feeding of the plant may be insured. Therefore, while the fact remains that fertilizers containing only the one form may not be the poorest, the chances are that those which contain all forms are likely to give more satisfactory results.

Pages 92–94: It [potash] is, however, a very necessary constituent of fertilizers, being absolutely essential for those intended for light, sandy soils and for peaty meadow lands, as well as for certain potash-consuming crops, as potatoes, tobacco, and roots, since these soils are very deficient in this element, and the plants mentioned require it in larger proportions than do others. * * *

Potash, as has already been stated in the discussion of phosphoric acid and nitrogen, exists in various forms, but it differs from the other elements in that its chemical form or combination seems to exert but relatively little influence upon the availability of the constituent. For example, it may be in a form of muriate or chlorid, of a sulphate or of a carbonate, and while there is a difference in the diffusibility of these different compounds—that is, a difference in the rate at which they will distribute in the soil before becoming fixed—there seems to be very little difference in the rate of the absorption of the potash by the plant. Nevertheless, the form of potash must be observed, because of the possible influence that the substances with which it combines may exert in reducing the marketable quality of the crop to which it is applied. This influence has been very distinctly observed, particularly in the growing of tobacco, sugar beets, and potatoes, and it has been shown that the potash in the form of a chlorid (or muriate) does exert a very deleterious effect, especially on tobacco.

Pages 129–130: In the purchase of mixtures consumers should demand that they be accompanied by a guaranty, because they are unable to determine the kind and proportion of the different materials entering into the mixture, either by its appearance, weight, or smell. In mixing, too, an opportunity is afforded for disguising poor forms of the constituents, particularly nitrogen; that is, in a mixture of nitrogeneous materials, potash salts and superphosphates, it would be a difficult matter to determine, by mere physical inspection, the proportion of the nitrogen which had been supplied in the form of horn meal and of blood, and the statement of the manufacturer on this point would be valuable in proportion to his reliability.

Page 149: An analysis may show simply the total amount of the constituent. This is not a sufficient guide as to the value of the mixture, for while it is not possible to indicate absolutely by analysis whether the organic nitrogen, for example, is derived from blood (which is one of the best forms), or from horn meal (one of the poorer forms), it is possible to show whether the nitrogen is derived from nitrate of from ammonia; whether the phosphoric acid is derived from a superphosphate or a phosphate, and whether the potash present is in the form of a sulphate or of a muriate. A high-grade or a low-grade fertilizer, for example, may be distinctly indicated by the analysis, since it is of a high grade if the three forms of nitrogen are present, if the total phosphoric acid is chiefly soluble in water, and if the poash has been derived from a sulphate or from a muriate.

Page 152: It is obvious, from what has been already pointed out, that the value of a fertilizer to the farmer depends not so much upon what is paid for it as upon the character of the material used to make it.

Page 175: A ton of wheat at $1 per bushel, will bring $33.33. Its sale removes from the farm 38 pounds of nitrogen, 19 of phosphoric acid, and 13 of potash. At prevailing prices for these constituents it would cost $6.50 to return them to the farm.

Pages 158–161: It will be observed that the schedule gives the cost per pound of the different forms of nitrogen and of high-grade organic nitrogenous materials; of nitrogen and phosphoric acid in ground bone and tankage; or available phosphoric acid in superphosphates, and of the actual potash in potash salts, and is a useful guide also in showing that the nitrogen, phosphoric acid, and potash contained in these materials can be purchased in ton lots for the prices mentioned. The valuation of mixed fertilizers, obtained by the use of this schedule, are entirely commercial; they are not intended to indicate even a possible agricultural value. * * *

Third. The chemical analysis does not show absolutely the sources of the materials, and thus it is difficult to place a true commercial value upon a mixture. This is especially true of organic nitrogen, derived from different materials, a uniform value is placed upon the total nitrogen found, whether it is derived from the best forms, as dried blood and dried meat, or whether derived from horn meal, ground leather, or other low-grade forms of nitrogenous materials. This encourages the use of low-grade products by unscrupulous manufacturers to the real detriment of the trade as a whole. * * *

Fourth. Any system of comparison of brands must leave a great deal to the judgment of the purchaser. He must interpret for himself whether he would rather that his phosphoric acid were derived from one source or another.

Page 167: The primary object in the use of a commercial fertilizer is to receive a profit from the increase in the yield of crops from the land to which it is applied; and this may be derived either from the immediate crop or from the larger yield of a number of crops. That the greatest immediate and prospective profit may be gained, a wide knowledge of conditions which have either a direct or indirect bearing upon the result is essential.

In fact, the controlling conditions surrounding the matter are so numerous and so various that it is impossible, with our present knowledge, to lay down positive rules for our guidance. At best, only suggestions can be offered.

Page 172: It must be remembered, then, that only general rules apply in the use of fertilizers upon soils of different classes, and that they are modified by both the chemical composition and the mechanical condition of the soil. The best use of a fertilizer—that is, the greatest proportionate return of plant food in the crop, all things considered—is obtained from its application upon soils that possess "condition" or that are well cultivated or managed. Full returns can not be expected when they are applied upon soils that are too wet or too dry, too porous or too compact, or too coarse or too fine. It is important that even the best soils should be properly prepared, and it is infinitely more important that those which possess poor mechanical condition should be improved in this respect, before large expenditures are made for fertilizers.

Pages 182–185: The one system of fertilization which has perhaps received the most attention, doubtless largely because one of the first presented, and in a very attractive manner, is the system advocated by the celebrated French scientist, George Ville. This system, while not to be depended upon absolutely, suggests lines of practice, which under proper restrictions may be of very great service. In brief, this method assumes that plants may be, so far as their fertilization is concerned, divided into three distinct groups. One group is specifically benefited by nitrogenous fertilization, the second by phosphatic, and the third by potassic; that is, in each class or group, one element more than any other rules or dominates the growth of that group, and hence each particular element should be applied in excess to the class of plants for which it is dominant. In this system it is asserted that nitrogen is the dominant ingredient for wheat, rye, oats, barley, meadow grass, and beet crops. Phosphoric acid is the dominant fertilizer ingredient for turnips, Swedes, Indian corn (maize), sorghum and sugar cane; and potash is the dominant or ruling element for peas, beans, clover, vetches, flax, and potatoes. It must be understood that this system advocates only single elements, for the others are quite as important up to a certain point, beyond which they do not exercise a controlling influence in the manures for the crops for the three classes. This special or dominating element is used in greater proportion than the others, and if soils are in a high state of cultivation, or have been manured with natural products, as stable manure, they may be used singly to force a maximum growth of the crop * * *.

Another system which has been urged, notably by German scientists, is based upon the fact that the mineral constituents, phosphoric acid and potash, form fixed compounds in the soil, and are, therefore, not likely to be leached out, provided the land is continuously cropped. They remain in the soil until used by growing plants, while the nitrogen, on the other hand, since it forms no fixed compounds and is perfectly soluble when in a form useful to plants, is liable to loss from leaching. Furthermore, the mineral elements are relatively cheap, while the nitrogen is relatively expensive, and thus that the economical use of this expensive element, nitrogen, is dependent to a large degree upon the abundance of the mineral elements in the soil. It is therefore advocated that for all crops and for all soils that are in a good state of cultivation, a reasonable excess of phosphoric acid and potash be applied, sufficient to more than satisfy the maximum needs of any crop, and that the nitrogen be applied in active forms, as nitrate of ammonia, and in such quantities and at such times as will insure the minimum loss of the element and the maximum development of the plant.

Page 186: Another system of fertilization is based upon the theory that the different plants should be provided with the essential elements in the proportions in which they exist in the plants, as shown by chemical analysis. Different formulas are, therefore, recommended for each crop, the constituents of which are so proportionate as to reach its full needs. This method, if care is taken to supply an abundance of all of the necessary constituents, may result in a complete though, perhaps, not an economical feeding of the plant, since it assumes that a plant which contains a larger amount of one constituent than of another requires more of that constituent in the fertilizer than of the others. It does not take into consideration the fact that the plant which contains a larger amount of one element than another may possess a greater power of acquiring it than one which contains a smaller amount.

Pages 189–190: The most expensive and irrational system of all, and one more commonly practiced than any other in general farming, may be termed that "hit or miss" system; if a "hit" is made there is a profit, if a "miss" the loss is trifling. In this system, no special thought is given to the character of the crop or its needs. If the farmer can afford it, he purchases a fertilizer, without regard to its composition, and applies it in very small amounts. If it happens to contain that element which is particularly needed for the plant to which it is applied, a profit is secured. In too many cases, however, the constituents added are already in abundance in the soil, or so little of the fertilizer is used as to preclude any profit.

Page 193: The lacking element can not be fully determined, except by direct experiments by the farmer himself. That is, no general principle can be depended on as an absolute guide. He should learn whether his soil is deficient in any of the elements, and, if so, which one should be applied to the different crops in his rotation. A careful study along this line, too, will show whether it is fertilization that is required to meet seeming deficiencies, for it frequently happens that the needs of the soil are not so much for added plant food as for better management of the soil in other respects.

Pages 197–198: The results of experiment which have been conducted with great care in a number of States show that where "extensive" methods are practiced certain elements need not be added in the fertilizers; that is, that the soil contains such an abundance of them that the plant is able to obtain a full supply, at least, for a long time. For example, it has been shown that on the chief sugar-producing soils of Louisiana and Mississippi, and on the cotton soils of Georgia and Texas, the addition of potash has been of less importance in the past than the other elements, and it frequently does not need to be included in the fertilizer, while phosphoric acid is always needed.

The results of field experiments on this plan in New Jersey, on reasonably good, loamy soils, indicate that phosphoric acid and potash are of much more importance in fertilizers for corn than nitrogen; whereas upon sandy soils nitrogen and potash are of relatively more importance than phosphoric acid; that is, even where "extensive" practice is used there are conditions where one or more of the elements are not required in order to secure maximum crops, which eliminates the necessity of an immediate outlay for those constituents that are not lacking. Where experiments of this sort have been carried out and the specific needs determined, it becomes necessary to assume that all of the constituents are required, and to apply the amounts and proportions of those which the general considerations of the soil, season, climate, and crop would seem to demand.

As already pointed out, the methods of fertilization here suggested, though in many instances apparently positive, are not to be interpreted as absolute rules, but rather to be used as guides, based upon the best information that it has been possible to obtain, both as a result of scientific inquiry and of practical experience.

Pages 211–212: The main point in this whole matter of fertilization is to understand that a fertilizer is a fertilizer because of the kind and form of plant food contained in it; and that its best action, other things being equal, is accomplished when the soil possesses good physical qualities, when the management is also good, and when systematic methods are planned and adopted. "Hit or miss" fertilization, even for these crops, may pay, and doubtless on the average does pay, as well as some other things that farmers do, but does not pay as well as it might if better methods were used.

APPENDIX B.

A SUMMARY OF THE GUARANTEED ANALYSES OF FERTILIZERS SOLD IN SEVERAL STATES.

In this review or analysis of the figures showing the composition of the brands of fertilizers sold in the several States, the guaranteed minimum compositions only are used, as these are usually expressed in whole numbers or even percentages, and as they in most cases agree very well with the amounts found by analyses. The figures for nitrogen occurring in some of the reports have been calculated to ammonia (NH_3) for purposes of comparison, and in a few cases small fractions of a percentage have been neglected and the result stated in the nearest whole number. None of the remarks or observations made in connection with the figures have been quoted from the official publications.

CONNECTICUT.[a]

During 1907 thirty-six individuals or firms have entered for sale in this State 279 brands of fertilizers, viz:

Special manures for particular crops	126
Other nitrogenous superphosphates	98
Bone manures and "bone and potash"	23
Fish, tankage, castor pomace, and chemicals	32
Total	279

Classification of the fertilizers analyzed.

1. Containing nitrogen as the chief active ingredient:
    Nitrate of soda.
    Sulphate of ammonia.
    Dried blood.

---

[a] Biennial Report, Conn. Agr. Expt. Sta., 1907–8.

1. **Containing nitrogen as the chief active ingredient—Continued.**
    - **Cotton-seed meal.**
    - **Castor pomace.**
    - **Linseed meal.**
2. **Containing phosphoric acid as the chief active ingredient:**
    - **Dissolved phosphate rock.**
    - **Basic slag.**
    - **Precipitated bone.**
3. **Containing potash as the chief active ingredient:**
    - **Carbonate of potash.**
    - **High-grade sulphate of potash.**
    - **Double sulphate of potash and magnesia.**
    - **Muriate of potash.**
    - **Kainit.**
4. **Containing nitrogen and phosphoric acid:**
    - **Bone manures.**
    - **Slaughterhouse tankage.**
    - **Dry ground fish.**
5. **Mixed fertilizers:**
    - **Nitrogenous superphosphates.**
    - **Special manures.**
    - **Home mixtures.**
6. **Miscellaneous fertilizers and manures:**
    - **"Vegetable potash."**
    - **Cotton hull ashes.**
    - **Wood ashes.**
    - **Lime and limekiln ashes.**
    - **Others, miscellaneous.**

Commercial valuations allowed by the station.

	Cents per pound.
Nitrogen in nitrates	18½
ammonia salts	17½
Organic nitrogen in dry and fine ground fish, meat, and blood, and in mixed fertilizers	20½
fine bone and tankage	20½
coarse bone and tankage	15
Phosphoric acid, water soluble	5
citrate soluble	4½
of fine ground bone and tankage	4
of coarse bone and tankage	3
of cotton-seed meal, castor pomace, and ashes	4
of mixed fertilizers, if insoluble in ammonium citrate	2
Potash as high-grade sulphate in forms free from muriate (or chlorids)	5
as muriate	4½

MASSACHUSETTS.

The following explanatory statement is taken from the official bulletin, giving the results of the fertilizer inspection for the season of 1907:[a]

The organic nitrogen in the mixed goods is valued as coming from the best grade of raw materials and is counted at 20½ cents per pound. This method of valuing the organic nitrogen in mixed fertilizers will, of course, give a too high value on those goods in which the organic nitrogen has been derived from low-grade materials which possess slowly available nitrogen. This seems to be the only course, however, at present, as the ordinary methods of analysis will not discriminate between the available and inert forms of organic nitrogen.

Soluble phosphoric acid is valued at 5 cents per pound, citrate soluble or reverted acid at 4½ cents, and the phosphoric acid which is insoluble in ammonium citrate (usually termed insoluble phosphoric acid) at 2 cents per pound. Potash is valued according to the form in which it is found present in the fertilizer. Whenever a potash test is reported in the tables without comment or footnote, it will be understood that sufficient chlorine was present to unite with all of the potash. Every brand of complete fertilizer is tested for chlorides, and if sufficient chlorine is found to unite with all of the potash, it is taken for granted that the potash exists in the form of muriate and is counted as worth 4¼ cents per pound. The presence of chlorine does not necessarily prove that it is in combination with the potash, but its presence in a fertilizer supposed and advertised to be free from chlorides or where the potash is said to be present as sulphate or carbonate is just as objectionable as though it was actually in combination with the potash. Whenever the potash is guaranteed to be present as sulphate and the analysis shows the presence of chlorine, a footnote has been used to indicate how much is present in each form. Wherever only very small quantities of chlorides are present the potash has been reported as sulphate. Potash in form of sulphate has been valued at 5 cents per pound.

Whenever the potash is guaranteed as carbonate a test has been made for chlorides and sulphates, and a footnote indicates how much potash is present in each form. Potash in form of carbonate has been valued at 8 cents per pound.

Whenever it was known that potash had been derived wholly or in part from organic sources, in mixed fertilizers, a total potash test has been made and will be found reported in a footnote. No attempt has been made to place a valuation on that portion of the potash which is insoluble in water. It no doubt has a commercial value, but as we have no basis for establishing its worth, the results have simply been reported without comment. It should not be understood that all of the potash in vegetable organic compounds is insoluble in water. As a matter of fact about 80 per cent of the potash in cotton-seed meal is recovered in a water-soluble potash test. * * *

The agricultural value of a fertilizer represents its crop-producing power, which is far from constant on all soils.

The beneficial effect of any fertilizer on a particular soil depends on whether the fertilizer in question contains those elements of plant food in suitable quantity and quality in which the soil is deficient. In other words, the supply of plant food in soils varies widely, and every user of commercial fertilizers must select his fertilizer according to the conditions of his soil and the requirements of the crop which he wishes to raise. We are often asked which is the best mixed fertilizer to use. The consumer can better answer this question for himself by a study of his soil conditions and crop requirements. A general statement may be made, however, to the effect that, all conditions being equal, the consumer should select those fertilizers which give the greatest amount of plant food in suitable and available forms for the least money. A study of the tables of analyses should furnish reliable data in making fertilizer selections. The tables show the quality and quantity of the various essential elements of plant food with the possible exception of organic nitrogen. Prescribed methods of analysis do not include a wholly reliable means of determining the availability of organic nitrogen, and in all valuations, in case of the mixed goods, it is assumed that the organic nitrogen is present in the best forms.

---

[a] Inspection of Commercial Fertilizers, Mass. Agr. Expt. Sta., Bul. No. 119, December, 1907.

The high-grade fertilizers will, as a general rule, be the most economical ones to buy, and the low-grade fertilizers will, ordinarily, be the most expensive ones. In the manufacture of the best goods only high-grade raw materials and chemicals can be used, as the formula has to be made up of compounds whose united composition will furnish the desired quantity and quality of plant food and whose combined weight must not exceed 2,000 pounds. On the other hand, in the manufacture of very low-grade fertilizers the necessary compounds to supply the percentage of nitrogen, phosphoric acid, and potash which is guaranteed might be supplied in 1,200 to 1,500 pounds of material of good quality, and the remainder, to make up the ton weight, will be a filler of some sort which oftentimes has no fertilizing value whatever. Besides this, the consumer is obliged to pay freight and cartage on low-valued and worthless material. Many low-grade goods contain a high percentage of phosphoric acid. It should be borne in mind that phosphoric acid is the cheapest of the essential elements of plant food and that some of the low-grade mixed goods contain an excess of this material. Cheap or low-grade fertilizers are sometimes made up of crude stock having a comparatively low commercial and agricultural value.

There were 317 brands of fertilizers entered for sale in the State. Of these, there were 249 brands of complete fertilizers, with manufacturers' guarantees of the percentage of phosphoric acid, ammonia (nitrogen), and potash, 155 of them being special brands for special crops. An analysis of these figures for the nitrogenous superphosphates is given herewith.

MAINE.[a]

The following explanatory statement is taken from pages 85–89 of the official bulletin, giving the results of the fertilizer inspection by the Maine station for 1908:

The law regulating the sale of commercial fertilizers in this State calls for two bulletins each year. The first of these contains the analyses of the samples received from the manufacturer, guaranteed to represent, within reasonable limits, the goods to be placed upon the market later. The second bulletin contains the analyses of the samples collected in the open market by a representative of the station.

In the tables which follow the discussion there are given the results of the analyses of the manufacturers' samples of licensed brands. The tables include all the brands which have been licensed to February 10, 1908. Dealers are cautioned against handling brands not given in this list without first writing the station. * * *

To produce profitable crops and at the same time to maintain and even to increase the productive capacity of the soil may rightly be termed "good farming." Many farmers are able to do this, and the knowledge of how to do it has been largely acquired through years of experience, during which the character of the soil, its adaptibility for crops, and the methods of its management and manuring have been made the subjects of careful study, without, however, any definite and accurate knowledge concerning manures and their functions in relation to soils and crops. * * *

Soils vary greatly in their capabilities of supplying food to crops. Different ingredients are deficient in different soils. The way to learn what materials are proper in a given case is by observation and experiment. The rational method for determining what ingredients of plant food a soil fails to furnish in abundance, and how these lacking materials can be most economically supplied, is to put the question to the soil with different fertilizing materials and get the reply in the crops produced. * * *

It is good farming to make the most of the natural resources of the soil and of the manures produced on the farm, and to depend upon artificial fertilizers only to furnish what more is needed. It is not good economy to pay high prices for material which the soil may itself yield, but it is good economy to supply the lacking ones in the cheapest way. The rule in the purchase of costly commercial fertilizers should be to select those that supply, in the best forms and at the lowest cost, the plant food which the crop needs and the soil fails to furnish.

Plants differ widely with respect to their capacities for gathering their food from soil and air; hence the proper fertilizer in a given case depends upon the crop as well as upon the soil. The fertility of the soil would remain practically unchanged if all the ingredients removed in the various farm products were restored to the land. * * *

---

[a] Maine Agr. Expt. Sta., Bulletin 153, March, 1908.

The term "form" as applied to a fertilizing constituent has reference to its combination or association with other constituents which may be useful, though not necessarily so. The form of the constitutent, too, has an important bearing upon its availability, and hence upon its usefulness as plant food. Many materials containing the essential elements are practically worthless as sources of plant food because the form is not right; the plants are unable to extract them from their combinations; they are "unavailable." In many of these materials the form may be changed by proper treatment, in which case they become valuable not because the element itself is changed, but because it then exists in such form as readily to feed the plant. * * *

The agricultural value of any fertilizing constituent is measured by the value of the increase of the crop produced by its use, and is, of course, a variable factor, depending upon the availability of the constituent, and the value of the crop produced. The form of the materials used must be carefully considered in the use of manures. Slow-acting materials can not be expected to give profitable returns upon quick-growing crops, nor expensive materials profitable returns when used for crops of relatively low value.

The agricultural value is distinct from what is termed "commercial value," or cost in market. This last is determined by market and trade conditions, as cost of production of the crude materials, methods of manipulation required, etc. Since there is no strict relation between agricultural and commercial or market value, it may happen that an element in its most available form and under ordinary conditions of high agricultural value, costs less in market than the same element in less available forms and of a lower agricultural value. The commercial value has reference to the material as an article of commerce, hence commercial ratings of various fertilizers have reference to their relative cost and are used largely as a means by which the different materials may be compared.

There were 209 brands of fertilizers placed upon the market, of which 186 brands were complete fertilizers containing phosphoric acid, ammonia (nitrogen), and potash, which we will call nitrogenous superphosphates. Of these, 68 brands were designated as special brands for potatoes, and 35 brands for corn, grass, and grain. An analysis of the guaranteed figures shows the following composition of the brands of fertilizers sold in the State of Maine:

Composition of nitrogenous superphosphates summarized.

NORTH CAROLINA.

There were 1,805 brands of fertilizers registered for sale in North Carolina in the spring season of 1908. The following explanatory matter or advice as to making suitable selections from this great mass of material is taken from the official bulletin giving the results of the inspection,[a] and is probably about all that can be safely and positively stated in a general way with our present knowledge of fertilizers, soil, and crops, but it is in strange contrast with the assurance and knowledge implied in the names and compositions of the brands put out by the different manufacturers:

The analyses presented in this bulletin are of samples collected by the fertilizer inspectors of the department, under the direction of the commissioner of agriculture, during the spring months of 1908. They should receive the careful study of every farmer in the State who uses fertilizers, as by comparing the analyses in the bulletin with the claims made for the fertilizers actually used the farmer can know by or before the time fertilizers are put in the ground whether or not they contain the fertilizing constituents in the amount they were claimed to be present. * * *

Water-soluble ammonia.—The main materials furnishing ammonia in fertilizers are nitrate of soda, sulphate of ammonia, cotton-seed meal, dried blood, tankage, and fish scrap. The first two of these (nitrate of soda and sulphate of ammonia) are easily soluble in water and become well distributed in the soil where plant roots can get at them. They are, especially the nitrate of soda, ready to be taken up by plants, and are therefore quick-acting forms of ammonia. It is mainly the ammonia from nitrate of soda and sulphate of ammonia that will be designated under the heading of water-soluble ammonia.

Organic ammonia.—The ammonia in cotton-seed meal, dried blood, tankage, fish scrap, and so on is included under this heading. These materials are insoluble in water, and before they can feed plants they must decay and have their ammonia changed, by the aid of the bacteria of the soil, to nitrates, similar to nitrate of soda.

They are valuable then as plant food in proportion to their content of ammonia and the rapidity with which they decay in the soil, or rather the rate of decay, will determine the quickness of their action as fertilizers. With short season, quick-growing crops, quickness of action is an important consideration, but with crops occupying the land during the greater portion or all of the growing season it is better to have a fertilizer that will become available more slowly, so as to feed the plant till maturity. Cotton-seed meal and dried blood decompose fairly rapidly, but will last the greater portion, if not all, of the growing season in this State. While cotton seed and tankage will last longer than meal and blood, none of these act so quickly or give out so soon as nitrate of soda and sulphate of ammonia.

Total ammonia is made up of the water-soluble and organic; it is the sum of these two.

The farmer should suit, as far as possible, the kind of ammonia to his different crops, and a study of the forms of ammonia, as given in the tables of analyses, will help him to do this.

The general character of the brands is as follows:

		Brands.
Material valued only for phosphate supplied:		
Acid phosphate, slag, and raw rock		236
Material valued only for nitrogen supplied:		
Nitrate of soda	45	
Sulphate of ammonia	11	
Fish scrap	6	
Dried blood	8	
	—	70
Material valued only for potash supplied:		
Kainit	61	
Muriate of potash	37	
Sulphate of potash	24	
Mixed salts	1	
	—	123

---

[a] Analyses of Fertilizers—Spring Season, 1908. The Bulletin of the N. C. Dept. of Agr., vol. 29, No. 4, Apr., 1908.

	Brands
Material valued only for phosphoric acid and nitrogen supplied:	
Bone and tankage	33
Mixed fertilizers:	
Containing nitrogen and potash	5
Containing phosphoric acid and potash	246
Complete fertilizers, containing phosphoric acid, nitrogen, and potash	1,002
	1,805

Of the 1,002 brands of complete fertilizers, 504 are special brands for special crops, as follows: Three brands for fruit; 176 brands for tobacco; 11 brands for peanuts; 38 brands for corn, grain, and grass; 94 brands for cotton; 68 brands for potatoes; 114 brands for truck.

Nearly half of the complete fertilizers, or nearly a third of the whole number of brands offered for sale, purport to be special brands for special crops.

The 246 fertilizers containing only phosphoric acid and potash have the following composition:

ALABAMA.

The following extracts from the Alabama law and comments on the same are taken from the official bulletin giving the results of the fertilizer inspection for 1908:[a]

"SEC. 6. No complete fertilizer, acid phosphate with potash, acid phosphate with nitrogen, or plain acid phosphate shall be sold in this State which contains less than 14 per cent plant food, namely, available phosphoric acid, nitrogen calculated as ammonia, and potash, either singly or in combination: *Provided*, That no complete fertilizer shall be sold in the State which contains less than 1.65 per cent of nitrogen, equivalent to 2 per cent of ammonia.

"SEC. 10. No person, company, dealer, or agent shall sell, expose, or offer for sale in this State any pulverized leather, raw, steamed, roasted, or in any other form, either as a fertilizer or fertilizer material, without first having made full and explicit statement of the fact and registration with the commissioner of agriculture and industries, and furnishing satisfactory proof that the nitrogen is sufficiently available and valuable for the purpose for which it is sold."

As a result of the enactment of the legislation referred to, the quality of the fertilizers found upon the market during the present season is considerably higher than heretofore, though the increase in plant food is chiefly in the phosphoric acid of the fertilizer. It is noted that owing to the change in the minimum limit of plant food some brands supplying the essential fertilizing constituents in entirely different proportions from those heretofore supplied by the brands upon the market have been listed for sale during the present season, and it seems quite probable that good results will follow the elimination of such fertilizers as the 10: 1: 1 goods. Fertilizers of this last-mentioned grade supply only 1 per cent each of potash and ammonia, and where the practice of applying one sack per acre of such a mixture has been adopted, only two pounds each of ammonia and potash are employed per acre of land. Inasmuch as many of our average soils to a depth of 6 inches will weigh about 2,000,000 pounds per acre, it will be seen that the application of such small amounts of ammonia and potash would add to the soil a relatively insignificant amount of plant food, and where these two particular constituents are needed by the soil they are usually needed in much larger proportions.

The situation with respect to the guaranteed composition of the brands on sale in Alabama is simplicity itself as compared with the figures for the four States already mentioned. There are 364 brands of complete fertilizers on sale in the State, of which 341 brands, or 94 per cent, have the following guaranteed composition:

---

[a] Annual Report on Fertilizers, Aug. 1, 1908, Dept. of Agr., Montgomery, Ala.

Number of brands.	Phosphoric acid.	Ammonia.	Potash.	Number of brands.	Phosphoric acid.	Ammonia.	Potash.
	Per cent.	*Per cent.*	*Per cent.*		*Per cent.*	*Per cent.*	*Per cent.*
251	10	2	2	7	9	3	3
7	10	4	4	17	9	2	3
17	10	3	3	21	8	2	4
5	10	2	3	16	10	2	4

The formula 10: 2: 2 far outnumbers all others, being represented by 251 samples, or 70 per cent of the whole number.

The extreme range in composition in the 341 brands as shown above is 2 per cent phosphoric acid, 2 per cent in ammonia, and 2 per cent in potash. In the remaining 23 brands the phosphoric acid goes up in 3 cases to 12 per cent and down to 6 per cent in 2 cases. Potash goes as low as 1 per cent in 3 brands. These are the extreme limits in composition of the complete fertilizers sold in the State. There are practically no special brands for special crops except cotton. The revenue from the sale of fertilizer tags for the fiscal year 1907-8 is given as $93,748.

GEORGIA.

The Georgia department of agriculture discusses quite fully the compositions of fertilizers and their relation to crops, and actually gives a number of special formulas for special crops, without, however, claiming to base these upon exact knowledge.[a]

The following extract from the state fertilizer inspection law is interesting in this connection:

"Sec. 4. Be it further enacted that the words 'high grade' shall not appear upon any bag or other package of any complete fertilizer, which complete fertilizer contains by its guaranteed analysis less than 10 per cent available phosphoric acid, 1.65 per cent nitrogen (equivalent to 2 per cent of ammonia), and 2 per cent of potash, or a grade or analysis of equal total commercial value; that the word 'standard' shall not appear upon any bag or other package of any complete fertilizer which contains, by its guaranteed analysis, less than 8 per cent available phosphoric acid, 1.65 per cent nitrogen (equivalent to 2 per cent ammonia), and 2 per cent potash, or a grade or analysis of equal commercial value; that the words 'high grade' shall not appear upon any bag or other package of any acid phosphate with potash which shall contain by its guaranteed analysis less than 13 per cent available phosphoric acid, and 1 per cent potash, or a grade or analysis of equal total commercial value; that the word 'standard' shall not appear upon any bag or other package of any acid phosphate with potash which shall contain, by its guaranteed analysis, less than 11 per cent available phosphoric acid and 1 per cent potash, or a grade or analysis of equal total commercial value; that the words 'high grade' shall not appear upon any bag or other package of any plain acid phosphate which shall contain by its guaranteed analysis less than 14 per cent available phosphoric acid; and lastly, that the word 'standard' shall not appear upon any bag or other package of any plain acid phosphate which shall contain, by its guaranteed analysis, less than 12 per cent available phosphoric acid. It is hereby provided that no complete fertilizer, acid phosphate with potash, acid phosphate with nitrogen, or plain acid phosphate shall be offered for sale in this State which contains less than 12 per cent of total plant food, namely, available phosphoric acid, nitrogen when calculated as ammonia, and potash, either singly or in combination: *Provided*, That in mixed fertilizers there shall not be claimed less than 1 per cent potash and 0.82 per cent nitrogen, when one or both are present in the same mixture."

The following rulings have been made by the commissioner, based upon the inspection law:

Fourth.—In case of goods containing 10 per cent available phosphoric acid, 0.82 per cent nitrogen, and 1 per cent potash, or such mixture 9 : 1.65 : 1, or

---

[a] Commercial Fertilizers and Chemicals, Season 1907-1908, Serial No. 46, Ga. Dept. of Agr.

8 : 0.82 : 3, or other combinations which do not reach a total commercial value equal to that of the standard fertilizer, which is 8 : 1.65 : 2, such mixtures are not to be designated by any grade at all. Such goods may be offered for sale and branded with any name the market desires to give, provided such name does not indicate that they belong to a high or standard grade.

Sixth.—In the case of goods containing less than 1.65 per cent nitrogen they may be branded as "ammoniated" goods, "guano" or "fertilizer," or other words implying that the same is an ammoniated superphosphate, provided they contain not less than 0.82 per cent nitrogen.

Seventh.—A goods containing 10 per cent available phosphoric acid, 0.82 per cent nitrogen and 3 per cent potash, can not be branded high grade, since it has not as high a commercial value as the legal high grade.

Eighth.—No manufacturer has the right to print the word "ammonia" at all on his sacks.

Sixteenth.—It is hereby ordered, in consonance with the spirit of section 8 of the law, that no cyanogen compounds, dried muck or peat, wool waste, tartar pomace, or Mora meal, or other material not recognized by scientific authorities as being available sources of plant food, shall be used in any fertilizer sold in this State. All manufacturers are warned against purchasing unfamiliar fertilizer materials without first inquiring of this department as to their character.

Under the title "Misleading brand names and a little advice on purchasing," the following occurs:

> It shall be borne in mind always that state valuations are relative and approximate only, and are only intended to serve as a guide. It is much to be desired that farmers should study the analyses giving the actual percentages of plant food more, and pay no attention whatever to names and brands.
>
> They should realize, for instance, that in nine cases out of ten brands known as "pure dissolved bone" contain not a particle of bone, but are made simply out of phosphate rock. They are every "whit and grain" as good as if they were made from bone, the available phosphoric acid from rock being just as available and identically the same as the available phosphoric acid from bone. The proof that such brands are not made from bone is that they contain no nitrogen, and if they were made from bone the percentage of nitrogen would be stated, and would be charged for. This is only one instance of the folly of being influenced by names and brands—many might be given.
>
> Remember that a multiplicity of brands is also expensive to the manufacturer, and you have to pay the cost in the long run. Study the market, select a time for purchasing when general trade in fertilizers is dull, club together with some of your neighbors, and then order from a reliable manufacturer, stipulating, if you have a preference, just what materials the goods shall be made from, and especially the guaranteed percentage of nitrogen, phosphoric acid, and potash. Let the maker call it anything he pleases.

The following proportion of plant food element for special crops is recommended by the department, although the caution is given that "every intelligent farmer will study his environment, his soil, and climatic conditions, and then use his best judgment."

Crop.	Phosphoric acid.	Ammonia.	Potash.
	Per cent.	*Per cent.*	*Per cent.*
Cotton	10	6	3
Corn	8	3	5
Wheat	5	6	3
Celery	5	8.5	8
Potatoes	7	7	8
Beets and lettuce	5	7	8
Cabbage, cauliflower, cucumbers, and melons	5	7	5
Spinach	8	6	6
Radish and turnip	7	6	8
Asparagus	7	6	8
Eggplant and tomatoes	6	6	7
Onions	5	6	8
Sweet potatoes	7	3.5	8
Beans and peas	7	3.5	7

Coming now to a consideration of the composition of the brands actually on the market, we find on the whole an astonishingly small variation in percentage composition of mineral plant food elements, although there is no possible way of determining how much variation there is in the material that went into the several brands.

There were 1,822 brands inspected, analyzed, and placed on the market for sale. Of these, 1,260 brands contain two or more plant food elements (phosphoric acid, nitrogen, or potash) in 106 combinations. There are 26 combinations, however, embracing 1,143 brands, or 90 per cent of the total, in which each combination is represented by 6 or more brands. Of the 1,260 brands containing two or more elements, 1,259 contain phosphoric acid, and 1,163 brands, or 92 per cent, contain from 8 to 10 per cent of phosphoric acid, as follows:

Brands.		Percentage of phosphoric acid.
Number.	Percentage.	
563	45	10
180	14	9
420	33	8

There are 77 brands, or 6 per cent, containing from 11 to 16 per cent, and 19 brands, or 2 per cent, containing from 7 to 5 per cent of phosphoric acid.

There are 1,259 brands containing potash, and 1,189 of these brands, or 93 per cent, contain from 1 to 4 per cent of potash, as follows:

Brands.		Percentage of potash.
Number.	Percentage.	
291	23	4
249	20	3
605	47	2
44	8	1

In addition to these, there are 54 brands, or 4 per cent, containing from 5 to 8 per cent of potash.

There are 987 brands containing nitrogen, and of these 947 brands, or 96 per cent, contain from 1 to 4 per cent of ammonia, as follows:

Brands.		Percentage of ammonia.
Number.	Percentage.	
34	3	4
85	9	3
696	70	2
132	14	1

In addition to these, there are 17 brands, or 2 per cent, containing from 5 to 8.9 per cent of ammonia.

There are 855 brands, or 89 per cent, of all the complete fertilizers in which the variation in composition is from 8 to 10 per cent phosphoric acid, 1 to 4 per cent ammonia, and 1 to 4 per cent potash, as follows:

Brands.		Percentage of phosphoric acid.	Percentage of ammonia.	Percentage of potash.
Number.	Percentage.			
255	27	10	3	2
242	26	8	2	2
90	9	9	2	3
44	5	10	3	3
34	4	10	1	3
28	3	10	2	4
23	2	8	1	3
23	2	10	1	1
23	2	9	1	2
18	2	10	4	4
18	2	8	2	4
18	2	9	2	1
14	1	9	3	2
13	1	9	2	2
12	1	8	3	3

Or, to put the matter in another way, there are 510 brands that differ only 2 per cent in the phosphoric acid, as follows:

Number of brands.	Percentage of phosphoric acid.	Percentage of ammonia.	Percentage of potash.
255	10	2	2
13	9	2	2
242	8	2	2

Then, there is in addition 254 brands in which the extreme variation from the above is 1 per cent ammonia and 2 per cent potash, as follows:

Number of brands.	Percentage of phosphoric acid.	Percentage of ammonia.	Percentage of potash.
28	10	2	4
8	10	2	3
34	10	1	3
1	10	1	4
6	10	1	2
1	9	2	4
90	9	2	3
2	9	1	4
6	9	1	3
23	9	1	2
18	8	2	4
8	8	2	3
6	8	1	4
28	8	1	3

It is apparent, therefore, that 764 brands, or 80 per cent, of the complete fertilizers sold in the State of Georgia have an extreme variation in composition—so far as the official records show, and the manufacturers' guaranty claim—of 2 per cent in phosphoric acid, 1 per cent in ammonia, and 2 per cent in potash. Furthermore, they are far below in ammonia and potash content the formulas proposed by the state inspection, as given on a previous page of this report.

The following is a list of the 255 brands having a guaranteed composition of 10 per cent phosphoric acid, 2 per cent ammonia (1.85 nitrogen), and 2 per cent potash:

List of brands having the guaranteed composition 10 : 2 : 2.

Athens High Grade Guano.
A A A A High Grade Guano.
Acid and Meal Mixture.
Acme High Grade.
Adair's Soluble Pacific.
Alligator Ammoniated Bone.
American High Grade Fertilizer.
10 : 2 : 2 Ammoniated Bone.

OBSERVATIONS ON THE DATA.

While the Georgia state department of agriculture recommends that from 200 to 500 pounds of fertilizer be used per acre, it may be safely said that the amount applied by the great majority of farmers is about 200 pounds per acre. Out of the 764 brands, such an application would add from 16 to 20 pounds phosphoric acid, 2 to 4 pounds ammonia, and 4 to 8 pounds potash to an acre.

If we assume that this fertilizer goes into immediate and complete solution and is distributed in the soil moisture to a depth of 6 inches from the surface, and if we assume further that the weight of an acre of soil 6 inches deep is 2,000,000 pounds and contains on the average 15 per cent of water, the maximum effect on the concentration of the soil moisture, diregarding the effect of the fertilizer on the solubility of the soil minerals and the absorbing power of the soil, will be approximately as follows: Phosphoric acid, 53 to 67 parts per million; ammonia, 7 to 13 parts per million; and potash, 13 to 27 parts per million.

So far as the ammonia and potash are concerned, these concentrations are comparable with the normal concentrations of the soil moisture; for phosphoric acid the figures are considerably higher.

It may be assumed that in a majority of cases when used an application of 200 pounds of commercial fertilizer increases the productivity of the soil. An application of 400 pounds or 600 pounds is undoubtedly more efficient, and successful applications up to 3,000 pounds per acre are employed on tobacco, truck, and other special industries.

What immediately concerns us here, however, is the differences in composition in the brands of fertilizers sold and the relative efficiency of these brands when applied to any particular field or crop. We have seen that of the 987 brands of complete fertilizers sold in Georgia markets, 255 brands, or 27 per cent, have the composition 10 : 2 : 2. Several of the dealers and manufacturers put out 6 or 8 more brands of this same composition. Do they differ and have different effects on the soil, and are they more efficient in connection with different crops? Under the state law and trade conditions they virtually have to be sold for the same price per ton. Officially, and so far as the public have certain knowledge, these 255 brands are all one and the same thing, and yet in all probability most of them differ in some essential character in composition and effectiveness, by reason of the material contained or mode and condition of mixture. We know that the different carries of phosphorus, nitrogen, and potassium have very different effects on soils and crops, and the time has come when it would be an advantage to the farmer, and equally to the manufacturer, to determine more nearly the relative effect of materials on soils and crops rather than to pursue longer the study of the elements—for after all it is the material which counts rather than the elements which go to make up the material. That is to say, it is not the potash but the potash salt. There are nitrogenous bodies and potash salts both extremely toxic to plants, but of the common materials which can be safely used for crops, some are more efficient on some soils and some on others, and more should be known about such matters.

Contrast now with 255 brands of the composition 10 : 2 : 2 the 242 brands of the composition 8 : 2 : 2, making together more than half the brands of complete fertilizers sold in the State. Is there a real difference in effect of these two classes due to the difference of 2 per cent of phosphoric acid? Or put the case more strongly still. Take the extreme limits in composition on the great majority (80 per cent) of fertilizers sold in the State, as given above

This would probably be 10 : 1 : 2 and 8 : 2 : 4, or we might take 10 : 2 : 4 and 8 : 1 : 2. The difference in the actual amount of nitrogen and potash is 100 per cent; and to make the same application double the amount of fertilizer would have to be applied in the one case than in the other. The difference is much less in the case of phosphoric acid, but apart from the question of the actual amount, does the difference in proportion shown by these small quantities have an appreciable effect on the soils and crops? In the above formulæ for example, as extreme cases, we might apply 2 pounds per acre of ammonia with either 4 or 8 pounds of potash, or we might apply 4 pounds of ammonia with either 4 or 8 pounds of potash. Would these proportional and actual differences show in their relative effect on the soil and plant? We have reason to believe from laboratory and greenhouse experiments in growing plants in solutions of pure cultures and in soil extracts that they would, but we do not know enough about it, and it is in this direction that further investigations should be made to bring some order out of the problem of the practical application of fertilizers.

AGRICULTURE AS A NATIONAL ASSET.

By Dr. B. T. Galloway,
Chief of Bureau of Plant Industry, United States Department of Agriculture.

SUMMARY.

The latest available figures show that the land area of the United States is, in round numbers, nearly 2,000,000,000 acres. The area in farms is approximately 850,000,000 acres, or 45 per cent of the total land. Irrigation, drainage, and utilization of arid and semiarid lands will probably make available for future use fully 50 per cent more land, or approximately 400,000,000 acres more.

The total wealth produced from the land in 1907 was, in round numbers, $7,500,000,000. As compared with the year 1899, the increase is 57 per cent. The increase in prices of farm products since 1900 is 37 per cent; the increase in prices of all commodities for the same period is 29 per cent; the increase in the value of farm land from the year 1900 to 1905, inclusive, is $6,131,000,000.

For the past five years the exports of agricultural products aggregated $4,565,000,000, reaching a maximum in 1907, when the value of the exports was $1,055,000,000.

The latest available figures show in the United States 6,000,000 farms. On 50 per cent of these farms production is falling off; on the other 50 per cent production is increasing. The average production of all crops has been increasing for forty years. Ninety per cent of the total increase in yields is brought about by 10 per cent of all the farmers.

Not less than 75 per cent of all the farmers in the country are engaged in some form of exploitive agriculture; that is, 75 per cent of all the farmers are taking from the land more than is being put back. Soil exploitation is an economic necessity in any new region or country and will continue where industrial pursuits other than agriculture are not encouraged, supported, and advanced. An equilibrium of industries means national prosperity. As an economic fundamental, selling must be accompanied by buying.

The wealth per capita of the farmer, the value of his land, his ability to select crops and systems of farm management, his power to supplant hand labor by machinery, and his ability to continually and profitably grow crops and at the same time build up and maintain the fertility of the soil are all directly dependent upon the mutual relation of agriculture to other industries. A constructive policy, therefore, for all industries means a constructive policy for agriculture.

The annual wastes from the farm aggregate an amount equal to the annual products, viz, $7,500,000,000. Wastage of soil fertility through erosion, the losses caused by insects, diseases, and other enemies, the losses through misdirected labor, lack of proper capitalization, lack of cooperation and organization in the selling of things produced and the buying of things used on the farm, lack of adaptation to environment or inability to shift crops and practices to changing economic conditions, and lack of knowledge and experience in handling, storing, and transporting corps, are some of the direct and contributing causes of the wastes in question. These wastes are a natural concomitant of our rapidly shifting economic conditions. With the development of other industries and increased population, larger demands for agricultural products and keener competition, the wastes will gradually disappear.

Every type of agriculture, from soil mining by individuals and organized groups of individuals to well-balanced, profitable, and constructive systems, is to be found in this country. The extremes cited are practiced through lack of knowledge and because under existing economic conditions both are found profitable in their respective localities.

Agricultural production in the United States will increase as rapidly as profits justify and the individual farmer shifts his methods and practices in conformity with better knowledge of the economic changes now taking place. The potentialities of production, through improved systems of farm management and increased efficiency of crops as the result of breeding, selection and adaptation, cooperation and organization in buying and selling, utilization of machinery and horsepower, prevention of direct wastes, etc., are sufficient at the present time to double the yields without any increase in acreage.

The problem at hand is not an increase in the number of farmers so much as an increase in the efficiency of the individual farmer and the maintenance of the proper relations between the labor of the farmer and that of other industrial pursuits. If 30 per cent of the labor of the country were engaged in agriculture it would tend toward higher efficiency of the farmer, better prices, better methods, and less direct waste than a larger percentage. A greater efficiency of the farmer and the consequent reclamation and conservation of the natural resources with which he comes in contact may be brought about by proper education, efficient organization, and effective cooperation. Proper education, organization, and cooperation means socializing rather than individualizing the farmer: the broadening of the training of the children of both city and country to the end of creating a just appreciation of all industries.

It means not only the full support of the state in bringing home to the individual farmer all the information that will make the land more productive, but the full support of the state in making the farmer a part of the world movement for social uplift. There are now many forces working to this end and these forces are constantly growing in power and influence. The moment is at hand for a constructive policy having for its object the federation of these forces through a properly equipped and organized federal agency.

AGRICULTURAL PRODUCTION WITH SPECIAL REFERENCE TO CROP RESOURCES.

By **Albert F. Woods**,

Bureau of Plant Industry, United States Department of Agriculture.

In discussing the question of agricultural production from the standpoint of the maintenance of our natural resources, we have to consider, first, those natural factors which are modified, either in the direction of improvement or deterioration, by their use, namely, plants, animals, and the soil, and possibly tools and methods; second, those economic and social conditions which stimulate or suppress the cultural effort and ability of men. This paper will deal briefly with the origin, status, and potentiality of our crop resources. Agriculture has been developed by man in proportion as his needs and desires have exceeded what nature unaided supplied.

PLANTS.

The origin of most of our staple cultivated plants is now believed to be fairly well known[a] and is in most cases of great antiquity. The wild races from which they were selected have in most cases been discovered, aggregating altogether approximately 300 species divided among a considerable number of genera. The list does not include quite a number of American wild fruits and grasses which have come into cultivation within recent years. Practically all of the older cultivated species, however, have been widely scattered over the earth, and have become broken up into a very great number of mutations or variations, some of them sufficiently marked to almost make them new species, if not genera. These selected and cultivated mutations have been handed on from generation to generation, undergoing constant selection and modification as the result of it, until now the number of forms or varieties is very great and represents adjustments to a great variety of climates, soils, cultural methods, uses, and other natural and artificial factors of environment where men have lived.

While the specific relationship of a crop plant is of great importance as indicating its possible range of adaptation, these modifications and adjustments to particular conditions are of far greater agronomic value. These modifications, while not usually considered by botanists as anything more than "place effects" and artificial productions, varieties or strains, are, nevertheless, of the greatest importance to man, as they enable him to live in places often otherwise uninhabitable and furnish material for food and clothing far superior to that obtainable from wild unimproved species. The only object in the life of the wild plant is to grow and reproduce itself, and no energy is lost beyond that necessary to insure this end. When the plant is brought under cultivation, the object is to increase some part of it in quantity or quality, or both, to meet some special need, and this is accomplished within certain limits in proportion to the duration, degree, and intelligence of the selective effort. The most valuable varieties of any crop plant for a locality are those which, as a result of long culture and selection in that locality, have adjusted themselves to the environment without losing their valuable qualities. In the case of cultivated plants, this adjustment is brought about in part by natural selection and partly by artificial selection. In the wild state, through countless generations of variation and natural selection and survival of the fittest, species and their varieties have become adjusted to the conditions under which they had to grow, the principal determining factors of growth being moisture and temperature range or fluctuation of the air and soil, the composition of the soil, disease and insect pests, competition with other species, etc. The power which the plant possesses to adjust itself to these conditions is a matter of the greatest importance, and the range within which a species or variety has the power of adjustment is limited. Crops, therefore, often differ in their relation to each of these factors and their combinations. Each species or variety is adapted to a certain combination and range of these conditions and reaches its best development only where the particular conditions to which the variety is adjusted are naturally or artificially supplied. When any condition varies beyond the limits of this adjustment the crop suffers in some particular correspondingly, and that condition becomes a limiting condition to that particular variety or strain.

---

[a] See general table of species, with their origin and the epoch of their earliest cultivation; taken from Origin of Cultivated Plants, by De Candolle, pp. 436-462, inclusive.

These physiological adjustments have not been carefully studied and measured for most of our crop plants and are generally recognized only in their broader relations. No one would attempt the commercial culture of cotton in South Dakota, but many growers buy their cotton seed from southern Texas or Louisiana for culture in northern Texas or Oklahoma, with the result that the long-season adjustment of the southern seed does not fit the shorter season farther north and much of the crop is destroyed by early frosts. Cotton or corn adjusted to the poorer uplands in Texas will go largely to stalk if planted on the richer, moister river bottoms. On the other hand, varieties adjusted to give a balanced growth on the bottom lands fail to give good results on the poorer and drier uplands. In very dry years, however, the upland varieties may do better on the bottom lands than the bottom-land varieties, and in very wet years the bottom-land varieties may succeed better on the uplands than the upland varieties.

As a crop approaches its limits with regard to any factor, the influence of the other factors, which tend to intensify or compensate the reaction to the limiting factor, becomes increasingly important. A variety of corn which can barely mature in the crop season of North Dakota and Minnesota is made more certain if planted on warm, well-drained soil and given very thorough culture. If the soil is heavy and cold or poorly drained, or the crop is planted late or poorly cultivated, it may suffer from early frosts. Farther south with a longer growing season, so far as the temperature limiting condition is concerned, the crop might do better on heavier, moister soil.

In nature related species often live under quite different conditions, certain species being adapted to different ranges and combinations of limiting factors, such as heat, moisture, drought, etc. It is often possible, therefore, by hybridization to produce species having intermediate characters or combining certain characters belonging to one species with certain characters belonging to another species in order to secure a variety adapted to conditions and uses to which neither of the species separately is adapted. When man began to select and cultivate wild species for his use, he, of course, started where he found the species growing wild, and had therefore a mixture of varieties corresponding to the wild forms. His first desire was to obtain a larger yield of fruit, seed, stem, leaves, or root, and he selected those individuals for seed which gave him the most in return for the care he could give them. They thus retained their natural vigor and resistance to limiting factors in their environment along with their specially selected characters. This is well illustrated in the strains of Indian corn as cultivated by the Indians at the time America was discovered and as grown by them still in Mexico and in Central and South America. It is also true of the cottons grown in the same countries. These aboriginal types still retain a wide power of variation, adaptation, and resistance to limiting conditions of their environment, especially where they have been cultivated for long periods exposed to those conditions. According to Cook.[a] many of these Indian tribes of Central America "are peaceable and sedentary, with highly developed agricultural instincts, which attach them closely to the land their fathers cultivated, and there is no reason to suppose that any very different condition existed in earlier times." It is thus evident that these aboriginal cottons and corns have been cultivated for long periods practically under the same conditions of seminatural selection. The characteristics and value of these varieties will be discussed later. The corns and cottons now in cultivation in the United States are selections and adaptations of some of these varieties, originally brought into the country by the Indians. They still retain a wonderful degree of adaptability and variation, which can be controlled in a very large measure by intelligent and long-continued selection.

In the Old World the same phenomenon is exhibited in the case of crops grown by the great masses of poor people, who have been obliged to live for long periods of time under conditions often extremely unfavorable and whose main object in life was to produce enough food to pay tribute with and to feed their families. Generation after generation lived under the same conditions, carefully saving every straw and seed. When some great drought or blight destroyed most of their crop the few remaining plants were not neglected and destroyed, but were carefully saved for seed, as it was often not possible for these poor people to obtain an outside supply. Thus as a result of centuries of such selection and survival of the fittest, we find these poor people possess varieties extremely resistant to the severe limiting conditions under which they were forced by necessity to live. A frequent change of seed, of location, or of economic conditions that would have permitted less careful saving of seed would have lost to the world these valuable products of unconscious natural selection.

---

[a] Cotton Culture in Guatemala, by O. F. Cook, Yearbook, U. S. Dept. of Ag. 1904, and Bureau of Plant Industry Bull. No. 88.

As civilization advances and economic conditions improve men often become more careless in the matter of seed selection. If cold or drought or disease causes a failure of the crop, the few straggling plants remaining are destroyed and seed for the next crop is secured in the market, with no knowledge of the conditions under which it was grown. It is, therefore, usually a mixture of seed from different sources, having been grown under conditions sufficiently different so that in a new locality the plants must go through a process of variation and adjustment before they will give satisfactory returns, but as a result of the same careless methods the plants never get a chance to become adjusted to the new conditions. The process of adjustment is mistaken for deterioration or so-called "running out," which in reality is the case where intelligent selection is not practiced. These careless methods have characterized the agriculture of the United States up to very recent times. The greater number of our farmers have given little or no attention to sources of seed or to intelligent seed selection. The rule is to sell the best and plant the culls, which, of course, is selection in the direction of deterioration. As a result of this, complaint is constantly being heard of varieties running out.[a] Many seedsmen have also been guilty of the same careless methods in buying and selling seeds of the great staple forage and cereal crops. Experimenters have also in most cases overlooked these fundamental facts of acclimatization and adjustment in the introduction and testing of new crops, and many a valuable plant resource has been pronounced worthless because it has not been adjusted to the particular conditions under which it was being tested. These adjustments are often physiological and may not change the general appearance or structure of the variety, but are apparent only in its response to the conditions of environment and culture. It is easy, therefore, to substitute such varieties for each other or to overlook them entirely, whereas, with a little careful observation, some of the mutations resulting from the attempt of the plant to adjust itself to its new conditions might prove to be well adapted to the new conditions and produce profitable crops if carefully selected.

As the demands made on the farmer are more exacting and he is rewarded in appreciation and money return for greater care, he rises to the situation. As the agriculture of the country settles down to more definite lines and to a more stable condition, these careless methods will disappear, and in fact have been rapidly disappearing in the past twenty years. This has been most apparent in the selection and improvement of flowers, fruits, and vegetables grown for our best markets. The development of fine varieties, and the care with which they are grown and marketed, has reached a point of the highest excellence in this country, owing to the appreciation of excellence and the high price which our cities are willing to pay for it. In the region of our great markets, like St. Louis, Chicago, Philadelphia, and New York, and the trucking lands tributary to them, the investment in the production of such crops and the annual returns aggregate several hundred million dollars. There have been also, since the earliest settlement of the country, here and there individuals who have taken an interest in the selection and improvement of our staple crops—corn, wheat, cotton, oats, rye, barley, etc.—and many new and improved varieties have been introduced, and have given good results when grown under conditions to which they were adapted. These plant resources are the foundation of our agriculture, and are of more value to us than any other natural asset.

---

[a] While failure to properly select is the cause of the real deterioration of varieties, the disappearance of old forms is also due to the development of better varieties, the old forms, therefore, being neglected in favor of the better strains. This is also responsible in part for the idea of the running out of varieties.

It will now be desirable to briefly review our principal plant resources.

INDIAN CORN.

Indian corn is the most widely cultivated and the principal crop plant of the United States. It is a native of tropical America, where a large number of varieties exist, many of which were adapted to conditions (including extremes of moisture, drought, and high altitude) under which the varieties now planted in the United States do not thrive. It is believed that some of these strains will be valuable, either on their own account or for hybridizing purposes with the strains we now have, in order to better adjust them to conditions where corn culture is now uncertain.

Prolonged production of pollen.—One important adaptation of these drought-resisting types of corn is the greater length of time during which pollen is produced. Although the tassels are much smaller than in our United States varieties, the same tassels continue to yield pollen for a period of several weeks, whereas our varieties may supply pollen for only as many days in dry localities or dry seasons. This character furnishes a protection against the loss of a crop through the occurrence of extremely dry, hot weather at the time of flowering, and may have much practical importance in the region to the south and west of our present corn belt, where the growing of our American varieties is prevented by dry climate and hot winds. In fact, the destruction of the pollen by drought and hot winds has been the cause of greatly decreased yields in the center of our corn belt, in Illinois, Iowa, Missouri, Kansas, and Nebraska. If greater drought-resisting qualities could be bred into some of our high-yielding strains of dent corns it would be of immense value, and there is no doubt that this can be accomplished. A study of the fluctuations in yield in the great corn States of the Ohio Valley, upper Mississippi and Missouri valleys, and the Great Plains shows that drought and hot winds are the principal limiting conditions to corn culture, and are often prolific causes of reduced yield. As will be seen by examining the table of annual yields, the great reductions in yield have been in years of severe drought during the growing season, and in those States or parts of States where the drought was most severe the yields have, of course, been lowest. (See article on this subject by the present writer, p. 227.)

In western Nebraska, Kansas, and the Dakotas the annual rainfall is usually not much greater than actually required for the production of average crop yields, and is the principal limiting factor of crop production in that region. The evaporation in the southern part of this area as compared with the northern part is nearly double, so that with the same rainfall the amount of available moisture for a crop will be much less in the southern than in the northern part of the Great Plains. With the same rainfall, therefore, we find the crop yields in the south of this area much less than in the north, owing to the fact that more of the water that falls remains in the soil in the north. The difference between the moisture-holding capacity of soils and the cultural methods adapted to conserve moisture is also brought out clearly in this western region in dry years. Where the soil has been prepared in the fall so as to absorb winter rainfall or melting snow, and cultivation methods have been adopted so as to conserve this water in the soil for the use of crops, good yields are often secured with very small summer rainfall, or, in some cases, even none at all. The different preparation of the soil and cultural methods are often apparent on farms side by side—one farmer raising a good crop on soils where the moisture has been conserved, and his neighbor, who has not followed proper cultural methods, having a total failure. The difference between varieties of plants adapted to growth under dry conditions and those adapted to moist conditions is also here clearly demonstrated.

While the effect of drought on yield is most marked as we approach the limits of available moisture, it is also considerable in the regions of normally heavier rainfall. Under careful experimental conditions at the Illinois Experiment Station, the average yield of 18 varieties was 29.4 bushels in 1887, 83.2 bushels in 1888, and 66 bushels in 1889. Meteorological conditions appear to have been largely, if not solely, the cause of these differences in yield.[a] The average yield for Champaign County, in which the experiment station is located, in 1887 was 20 bushels; in 1888, 42 bushels; in 1889, 35 bushels. The difference between these average yields in the county and at the station may be fairly considered to represent the difference between the best standard culture and the average culture, while the fluctuation between years shows the effect of season, 1887 being a drought year.

Similar fluctuations occurred during the drought of 1894. The average for the northern division of Illinois was 31 bushels, the lowest yield being 15 bushels in Lake County. The average for the central division was 35 bushels, the lowest being 10 bushels in Coles County, and the highest 50 bushels in Calhoun. The average for the southern division was 18 bushels, with a minimum of 3 bushels in Bond County and a maximum of 28 in Madison County.

The soils of northern and central Illinois are much better adapted to absorb and retain moisture than those of the southern part of the State, and the relative evaporation follows the same law as indicated farther west, so that a study of crop yields, even with the same rainfall, in the northern and southern parts of the State shows less effect of drought in the north and greater effect in the south under otherwise the same conditions, the effect, of course, being intensified where the soil is favorable or unfavorable to moisture absorption and retention, and increases in yield also being secured in dry years by those cultural methods which tend to conserve moisture.

---

[a] See Abbe, Climate and Crops, p. 334.

In the Southern and Southeastern States, in the cotton belt, where yields are very low as a rule, the moisture factor also plays a considerable rôle. Although the rainfall is much higher than in the northern belt, it evaporates quicker, and the soils as a rule are less retentive of moisture, being in most localities depleted in humus. According to A. J. Henry,[a] "the smallest amount of rainfall that may be expected in the great corn and wheat regions of the central valleys does not vary greatly from 9 to 10 inches (from April 1 to September 30). In the South Atlantic and Gulf States the fall in the year of least rain ranges from a maximum of 20 inches in central and northern Florida to less than 15 inches in the Mississippi Valley and a considerable fringe of country to the westward. The amount of rain that falls in the year of severe drought in the greater part of the Southeastern States is sufficient for the growth and maturity of staple crops, if properly distributed. Success in agricultural pursuits, so far as conditioned upon the rainfall, should therefore be more easily achieved in the Southeastern States than elsewhere, particularly in regions of precarious rainfall." The shallow spring plowing characteristic of the cotton States is not adapted, however, to conserve the water that falls, so that there is seldom a year in which crops do not suffer more or less from drought. The general character of the rainfall of the Southeast is conducive to the development of rather soft growth, evaporating water with considerable rapidity, so that any lack of moisture at the roots is much more evident and injurious than would be the case where the air is drier normally. Experiments conducted through the southern area by the Department of Agriculture and the state experiment stations have shown conclusively that deep plowing, the use of barnyard manures and legumes or other green crops to increase the decaying organic matter and humus of the soil, with shallow summer cultivation, are alone sufficient to raise the average yield of corn in these States to the average of the best corn States.

American strains of corn.—From whatever types in Central America or South America our varieties of corn now in cultivation may have come, we now have in our great central corn belt numerous strains or adaptations of the greatest value. Some of these have become fairly well known, but there are many others which have been grown in certain localities for many years which simply require a little careful selection to bring out their highest yielding capabilities. The corns that we now have fall into six generally recognized groups, as follows: Pop corns, flint corns, dent corns, soft corns, sweet corns, and starchy sweet corns. All of these have their valuable features and uses. The flints and pop corns are generally considered to be cool-region corns, having been grown successfully as far north as Quebec. The flint corns were first introduced and cultivated in the North Atlantic region by the Indians, and has remained to the present time the principal type cultivated in New England. These northern flint strains have thus become adapted to the short seasons of the North. Similar flint varieties, however, were also grown by the Indians in the central and southern localities, in the

See also Relation of precipitation to yields of corn, Yearbook, U. S. Dept. Agr., 1903, pp. 215–224.

Gulf region, and Central and South America, the southern forms having a longer growing season. The flint varieties are lower yielders and less desirable in other characters than the dents.

The dent varieties are generally considered to be longer season sorts and have been cultivated generally south of New York, Minnesota, and the Dakotas. On account of their better quality and higher yielding power, they have been gradually pushed north into Minnesota, Wisconsin, and the Dakotas, and as a result of careful selection high-yielding strains maturing in ninety to one hundred days have been secured. One ninety-day type, bred by the Department of Agriculture in Wisconsin and Minnesota, has yielded as high as 90 to 100 bushels of shelled corn per acre in field tests. A strain developed in Connecticut from Illinois seed of Reid's Yellow Dent has been selected at Hockanum, Conn., since 1905. Very few ears matured in 1905. These were saved and planted in 1906 and practically all the crop matured, yielding 121 bushels of mature shelled corn per acre—more than double the yield of flint corn grown under exactly the same conditions. It is evident, therefore, that high-yielding, quick-maturing dent corns can be developed by careful selection for the colder Northern States.

A similar high-yielding strain of white dent was developed by a farmer near Gainesville, Ga., by planting together four varieties of dent and allowing them to cross. A strain was selected showing evidence of being a cross, which after a few years' selection under the Georgia conditions has proved to be one of the finest dent strains yet developed, yielding from 75 to 100 bushels of shelled corn per acre in field tests, some of the ears weighing over 2 pounds. This is more than double the yield of the unselected dent varieties of the same region grown under the same conditions, and from seven to ten times the average yield of the State.

A number of important selections have been made from time to time which have had an important influence on corn culture, especially in the upper Missisippi and Missouri valleys. Among these may be mentioned the following: Leaming, a deep yellow dent, selected by J. S. Leaming, Wilmington, Ohio, in 1826; Reid's Yellow Dent, selected by J. L. Reid, Delavan, Ill., in 1846; Golden Eagle, a yellow dent, selected by H. B. Perry, Toulon, Ill., in 1871; Boone County White, selected by James Riley, Thornton, Ind., in 1876; Riley's Favorite, a white dent, introduced by James Riley in 1885; Pride of the North, a white dent, introduced by F. A. Warner, Sibley, Ill., 1890. These were principally selections of good individuals of the various types in common cultivation in the region, some of them probably resulting from crosses of different strains. Corn being pollinated by wind-borne pollen, the varieties, of course, often cross, which causes considerable variation and increased vigor. By selecting the best individuals and growing them by themselves for several generations fairly pure types can be developed of much greater producing power than the average. Every strain, however, must be developed under the same conditions in which it is to be grown in order to get the greatest returns from it. This adjustment readily takes place as a result of a few years of intelligent selection.

Investigations and demonstrations carried out in all sections of the United States by the Department of Agriculture and the state experiment stations have shown beyond a doubt that the present average yield of corn per acre could be doubled, with practically no increase in work or expense, by giving careful attention to seed selection and vitality and cultural methods. In our principal corn-growing States corn is planted 3½ feet apart each way, making 3,556 hills per acre. Three stalks to a hill is considered a perfect stand, and with good, vigorous seed it is not difficult to secure on an average three good healthy stalks. If one in three of these stalks produces a small 6-inch or 7-inch ear weighing only a little over 9 ounces, the yield would be 28.8 bushels to the acre. This is the highest average yield for the United States, and occurred in 1905. This, of course, is an exceedingly small amount of grain to secure from three stalks. The average yield for the past forty years has been 25.2 bushels. New Hampshire and Vermont have averaged 35 bushels, fluctuating from 21 bushels in years of drought to 45 bushels in the most favorable seasons, and have shown a gradual increase from 1867 to date. The yields for Ohio, Indiana, Illinois, Michigan, Wisconsin, Minnesota, and Iowa have averaged from 31 to 33 bushels for the entire forty years, fluctuating from about 20 bushels in the driest years to about 40 bushels in the best years. Missouri, Nebraska, Kansas, Kentucky, and Tennessee follow slightly below the States just mentioned, the fluctuations, however, being greater in those States more subject to drought, falling as low as 7 to 10 bushels in Kansas and Nebraska and running as high as 42 to 43 in the same States. The lowest average yields are in the Southern States: Virginia, 19.2 bushels, fluctuating from as low as 13 bushels in dry years to as high as 25 in good years; North Carolina, falling as low as 9 bushels in dry years and running up to 16 bushels in favorable years; South Carolina, falling as low as 6.9 bushels in dry years and running up to 12 bushels in good years; and similar low yields in Georgia, Florida, Alabama, Mississippi, and Louisiana; Texas and Arkansas being a little higher.

The most careful selection of seed has been practiced in Illinois, Indiana, Nebraska, and Kansas, but even in these States the work has not continued long enough to be definitely brought out in general statistical data, but the difference is easily ascertainable in comparing individual growers who use selected seed and good methods with those under the same conditions using ordinary seed and ordinary methods. Good growers who carefully select their seed often obtain a yield of 80 to 100 bushels of shelled corn per acre. It is easy to produce strains that will average three or even four 9-ounce ears per hill of three stalks, but these are very small ears, and strains are very easily developed which produce ears averaging a pound, some of the ears running up to 1½ or 2 pounds. This average is frequently reached and exceeded under identically the same conditions of soil, climate, and culture that with ordinary strains give 40 to 50 bushels or less per acre. With careful attention to seed selection and testing[a] still greater average production for the United States could be reached with little additional cost and greatly increased profits even at present prices.

It is not argued, however, that it is desirable to make any such increase in the total production as this would imply, as the present production is about equal to the demand. An excess over ready demand has a tendency to reduce prices, which is followed by reduced acreage the next season, with a gradual rise in price, followed by increased acreage again. This fluctuation is shown by the tables on yield and prices of corn in the 1907 Yearbook of the Department of Agriculture.[a] However, if one acre could be made to produce as much as two do now, the other acre could be devoted to some other paying crop. Just as much corn would then be produced as at present, with the cost of production per bushel greatly reduced, and the profits, therefore, at present prices greatly increased. It costs little more to plow, harrow, plant, and cultivate an acre for a 100-bushel crop than it does for 40 bushels, and the land tax and rent are the same. These are the heavy fixed charges. Accurate data on the cost of production of farm crops are scarce. The most carefully secured information is to be found in Bulletin 48 of the Bureau of Statistics, U. S. Department of Agriculture, and Bulletins 97 and 109 of the University of Minnesota Agricultural Experiment Station. The following tables are taken from Bulletin 97 of the Minnesota Experiment Station:

These figures were based on 40 to 45 bushel yields in 1902, 1903, and 1904. There is not a great deal of difference in the tonnage of stalks between the 40-bushel crop and the 100-bushel crop, the difference being principally in the number and size of the ears. If the stalks are left on the ground, or if they are fed to stock and the manure returned to the ground, the only difference in fertilizer removal will be in the nitrogen, phosphoric acid, and potash in the grain. If the corn is fed and the manure returned to the ground, the loss of fertility would be a negligible quantity. The only other increased cost in caring for a large yield as compared with a small yield is in the case of hand husking and hauling of the product, a method now less followed than formerly, but one which the experiments above referred to indicate is more profitable than the cutting, binding, and shredding. It would not cost as much, however, to husk 100 bushels from 1 acre as from 2 acres, and it would not cost twice as much to husk 100 bushels from 1 acre as to husk 50 bushels from 1 acre, especially if the increased yield was due in part to larger-sized ears. If the harvesting is done by machinery, there would be practically no additional cost in harvesting a 100-bushel crop as compared with a 50-bushel crop. It is evident, therefore, that it would be highly profitable to reduce acreage and increase yield, and that the price could even be considerably reduced and a good profit made. As better and more careful methods of seed selection and culture come into vogue, it is possible that with the higher yields per acre thus secured the price of corn may fall considerably and still a larger profit might result in much the same way as the increase in the efficiency of labor-saving machinery.[a]

All of the investigations conducted by the Department of Agriculture and by the state experiment stations show clearly that where corn is continually cultivated on the same land the yield per acre is greatly reduced. Continued cultivation is especially destructive of humus and reduces the immediately available plant-food elements—nitrogen, phosphoric acid, and potash. The decaying organic matter resulting in the humus sets free in the soil the other elements of plant food from the only slightly soluble soil particles. It is, therefore, exceedingly important to maintain a sufficient amount of decaying organic matter in the soil to insure its best physical condition and the ready supply of plant food through its direct action.[a] As stated above, the first appreciable effect of this constant cropping is the lowering of the humus content of the soil, thus decreasing the nitrogen, and especially decreasing the power of the soil to absorb water and air. This brings about shallower rooting of the corn and makes it less resistant to fluctuations in moisture. The soil dries out more easily and during rains becomes too wet, excluding the air, bakes easily, and is more difficult to keep in tilth. The bacterial life of the soil is thus greatly reduced, resulting in the slower and imperfect decay of organic matter and the formation of nitrates, and a consequent reduction of the solution through bacterial and root action of the other elements of plant food in the soil. The earthworm fauna, which is so necessary to the proper development of humus and soil aeration, is also greatly reduced through the same causes, thus intensifying the unfavorable conditions. As these changes progress the bacterial and animal life changes and species become predominant that are unfavorable to the crops. The nitrifying and ammonifying bacteria become less active or are altogether suppressed, while the denitrifying and nitrite-forming species develop. The latter are well known to be injurious to plant roots. The earthworms die out and soon the life of the soil is gone. It becomes pasty and dead. Fungi often injurious to crops develop rapidly under these conditions, as in the case of the root-rot of Texas, which destroys several million acres of cotton each year. Crops growing in these pasty black adobe soils can not get enough air for the deeper roots, which, thus weakened, are attacked by the fungi present. Deep fall plowing, with a liberal use of barnyard and green manures, partially corrects the trouble and enables the plant to better resist the disease, but most of these soils, after they once get into this condition, also need, in addition to the cultural methods suggested, reinoculating with the natural flora and fauna of good fertile soils where active decay of organic matter by the right bacteria is taking place. These may be partly provided through manure, but it is often necessary to use either soil or cultures of the right forms.[b]

Constant cropping without rotation, even where there is no serious deterioration of the soil, may also cause the accumulation of insect, animal, and fungous pests of various kinds until it becomes impossible to grow the crop at all on such infected areas. The accumulations of nematodes and root insects are about the only injurious forms in the case of corn, but in the case of other crops, as will be discussed later, numerous other disease organisms cause serious trouble, as in the case of the cotton wilts, flax wilt, etc.

WHEAT.

The most careful investigations have indicated that wheat probably originated somewhere in the region of the Euphrates in extremely ancient times. From this region it gradually spread in all directions and is occasionally found in some of its various varieties in the earliest prehistoric remains of nearly all European, Asiatic, and North African countries. Its great value as food and the ease with which it can be carried from place to place, the facility with which it adjusts itself to changing conditions, have all resulted in the development of an immense number of varieties and strains. Even in the earliest prehistoric remains representatives of several distinct strains are found, indicating a very ancient culture.

For purposes of classification and description, eight fairly distinct groups, corresponding to eight botanical species, are recognized:

(1) Common bread wheat, *Triticum vulgare.*
(2) Club or square head, *T. compactum.*
(3) Poulard, *T. turgidum.*
(4) Durum, *T. durum.*
(5) Polish wheat, *T. polonicum.*
(6) Spelt, *T. spelta.*
(7) Emmer, *T. dicoccum.*
(8) Einkorn, *T. monococcum.*

While these large groups are generally considered as species, it must be understood that they probably originated from possibly one or two very closely related natural species, and the modifications resulting in the present rather distinct groups have been the result of long-continued culture and selection under different conditions. However, on account of the exceedingly long period of culture involved, the groups have become as well fixed as natural species.

As a food plant, wheat is even more important than Indian corn, and the demand for it is greater than that of any other cultivated crop. Many statistical studies have been made showing the relation between supply and consumption and the possible world production. It is evident that, with the increasing population of the wheat-using world under the conditions of modern life, there is some danger of the production falling below the demands for consumption. This matter has been discussed in great detail by Crookes.[a] In most of these studies, however, several important considerations have not been given due weight. The most important of these is the improvement in yield through the use of varieties carefully selected for high-yielding power for each locality where the crop is to be grown. This is particularly applicable to the wheat culture of the New World and Australia, where wheat is a more recent introduction and where in many cases it has not become fully acclimatized.

The second important factor is in the improvement of cultural methods, which is applicable throughout the world.

In 1899 Crookes[b] wrote: "The present acreage devoted to the world's growth of wheat is about 163,000,000 acres. At the average of 12.7 bushels per acre this gives 2,070,000,000 bushels. But thirty years hence the demand will be 3,260,000,000 bushels, and there will be difficulty in finding the necessary acreage on which to grow the additional amount required. By increasing the present yield per acre from 12.7 to 20 bushels we should, with our present acreage, secure a crop of the requisite amount." It is interesting to note, however, that for 1902 the production for the world reached 3,124,422,000 bushels, the largest crop ever produced. This falls only a little short of Crookes's estimate of the requirements by the year 1930, and the total production of the world has not fallen below this point to date, being 3,189,813,000 in 1903, 3,152,127,000 bushels in 1901, 3,320,959,000 in 1905, 3,435,401,000 in 1906, and 3,108,526,000 in 1907. This increase is due in part to increased acreage and in part, though very slightly, to increased production per acre by the use of better methods. The following table[a] gives Crookes's estimates, based on the assumption that the population unit consumption and steady development would increase during the forty-three years beginning with 1899 as they had increased since 1871 up to the date of his forecast:

---

[a] See The Wheat Problem, by Sir William Crookes. 1900.
[b] Loc. cit., p. 40.

Date.	Bread eaters.	Food and seed required per unit (bushels).	Requiring bushels of wheat.	With yields averaging 12.7 bushels, acreage required.
1871	371,000,000	4.15	1,540,000,000	121,000,000
1881	416,000,000	4.38	1,822,000,000	143,000,000
1891	472,600,000	4.50	2,127,000,000	167,000,000
1898	516,500,000	4.50	2,324,000,000	183,000,000
1901	536,100,000	4.50	2,412,000,000	190,000,000
1911	603,700,000	4.50	2,717,000,000	214,000,000
1921	674,000,000	4.50	3,033,000,000	239,000,000
1931	746,100,000	4.50	3,357,000,000	264,000,000
1941	819,200,000	4.50	3,686,000,000	290,000,000

According to these figures the requirement in the year 1941 will be only 3,686,000,000 bushels, necessitating an acreage of 290,000,000 with an average yield of 12.7 bushels per acre, and feeding 819,200,000 bread eaters. Of course, these figures might be considerably modified at the present time, but they are perhaps as accurate forecasts as could be made of future requirements were the estimates to be projected beyond the present date as these were beyond the date on which they were figured.

The difficulty in all these figures is that there are immense areas in various parts of the world that are not considered at all adapted to wheat growth which can be made available when necessity demands. This is well illustrated by the Great Plains area west of the one hundredth meridian. This area, which at the time Crookes's figures were made was not considered available for wheat production, is now yielding over 50,000,000 bushels of one variety alone of the durum group, and improved methods of dry-land agriculture are making it possible to produce the hard winter wheats in the same area, so that it is exceedingly difficult even at the present time to estimate the potential wheat production of a strip of territory 300 miles wide exending from our northern border to the southern. On the basis of figures compiled by John Hyde, of the Bureau of Statistics, Department of Agriculture, included in full in Crookes's discussion of the wheat problem before referred to, the following statements are made:[b]

---

[a] Loc. cit., p. 244.

[b] Loc. cit., p. 195 et seq.

That the population of the United States in 1931, exclusive of colonial possessions or dependencies, will be at least 130,000,000 is as certain as any future event can be, but it is not nearly so easy a matter to forecast the agricultural production of that period. * * * What contribution, if any, will our farmers be able to make to the wheat supply of other countries when the time comes that provision has to be made for the varied requirements of a home population more than twice as large as that at the last federal census?

Those requirements will include a wheat crop of 700,000,000 bushels, without a bushel for export; an oat crop of 1,250,000,000 bushels; a maize crop of 3,450,000,000 bushels, and a hay crop of 100,000,000 tons, all for domestic consumption; with cotton and wool, fruits and vegetables, dairy and poultry products, meat, and innumerable minor commodities in corresponding proportions. The area necessary to the production of the three principal cereals alone will be over 15 per cent greater than the enormous total acreage devoted in 18[illegible] to grain, cotton, and hay, while the mere addition of the two last-mentioned products and of the minor cereals will call for an acreage exceeding the total area of improved land in farms at the present time.

But what, it may be asked, is to prevent either (1) any necessary extension of the areas in farms, or (2) the bringing under cultivation of that large residue of unimproved land which amounted at the last federal census to no less than 42.5 per cent of the total farm area?

The great fact that underlies the enormous productive capacity of the United States to-day is, of course, the transfer from government ownership to individual proprietors, within a single generation, of a body of land hundreds of millions of acres in extent, and for the most part of extraordinary fertility. But, amazing as has been the increase in the farm area of the country during the last thirty years, it has not been sufficient even to keep pace with the growth of population. The addition of 128,300,000 acres, or 31.48 per cent, to the area in farms between 1870 and 1880 only increased the area per capita of population from 10.57 to 10.69 acres. By 1890 the area, notwithstanding a further addition of 87,100,000 acres, or 16.25 per cent, amounted to only 9.95 acres per capita, and the census of 1900 will almost certainly find it under 9 acres.[a]

That for general agricultural purposes the public domain is practically exhausted, and that, consequently, there can be no further considerable additions to the farm area of the country is too well-established a fact to be the subject of controversy. Of the entire area undisposed of, 72.7 per cent is in States wholly within the arid region, and all but a small part of the remainder is desert, mountain, or at best suitable only for grazing purposes. In Kansas, out of 1,061,000 acres undisposed of, only 116,000 acres are east of the one hundredth meridian, and these are described as broken and for the most part sandy. In Nebraska, 10,548,000 acres are still open to settlement, but not one acre in seven is in a region of sufficient rainfall for general agricultural purposes, and the best of the land is described by the General Land Office as fit only for grazing. In North Dakota the vacant land amounts to 20,575,000 acres, but on little more than one-tenth of this area could irrigation be dispensed with, even if the land were otherwise adapted to general farming. In Oklahoma, the youngest of the Territories, and the one containing the largest addition to the farm area of the country that has been made within many years, of the 7,007,000 acres of government land still vacant, 3,250,000 acres lie between the ninety-ninth and one hundredth meridians and a like amount, making altogether 93 per cent of the whole, west of the one hundredth.[b] The vacant land in the Pacific States amounts to 91,843,000 acres; but of the 42,500,000 acres in California, 19,000,000 acres are "barren, irreclaimable wastes," 19,875,000 acres "desert and grazing," and 3,628,000 acres "woodland and forest;" the 35,898,000 acres in Oregon include 17,067,000 acres of "desert and grazing," and 18,831,000 acres of "woodland and forest," while the 13,443,000 acres in Washington comprise 3,847,000 acres of "desert and grazing," and 9,596,000 acres of "woodland and forest."

It should not be forgotten in this connection that it is no longer the policy of the American people or of its representatives in Congress to permit the con-

---

[a] The census for 1900 shows the per capita acreage to be a little over 11 acres.

[b] As previously stated, a large proportion of this land west of the one hundredth meridian is now believed to be available for dry-land agriculture and is already contributing over 50,000,000 bushels of one variety of wheat alone to the supply of the United States, over 20,000,000 bushels of which have gone into the export trade.

> tinued destruction of the national forests without regard to the needs of the future. It should also be borne in mind that, according to the United States Geological Survey, the entire water supply of the Pacific States available for irrigation is only sufficient for some 23,000,000 additional acres, or about 1 acre in 4 of the unappropriated public lands in those States. In the entire arid region the available water supply, as similarly estimated by the United States Geological Survey, is only sufficient for the irrigation of 71,500,000 additional acres, or 1 acre in 7½ of the area undisposed of. * * *
>
> The extent to which the total farm area of the country can be increased by the reclamation of desert lands will therefore be seen to be very small, if not absolutely insignificant; indeed, it is a question whether it will be sufficient even to counterbalance those constant encroachments upon the productive area which arises from the growth of cities, the building of railroads, and the general development of commerce and nonagricultural industry.

Mr. Hyde then goes on to discuss the great body of unimproved farm land. In the census of 1890, which he had under consideration, there were about 115,000,000 acres of unimproved land in the various farms of the different regions of the United States. The distribution of this land is very ununiform and the extent to which it may be made available is found to differ widely. In Illinois and Iowa it is estimated to be between 15 and 20 per cent of the total farm area; in New York, New Jersey, Pennsylvania, Delaware, Ohio, Indiana, Kansas, and Nebraska, between 20 and 30 per cent; in Vermont, Connecticut, Maryland, Michigan, Missouri, North Dakota, and South Dakota, between 30 and 40 per cent; in Massachusetts, Rhode Island, Kentucky, Wisconsin, and Minnesota, between 40 and 50 per cent; and in Maine, New Hampshire, Virginia, and West Virginia, between 50 and 60 per cent.

> Assuming [says Mr. Hyde][a] that the entire region will, under the influence of high prices, have 85 per cent of its total farm area brought under cultivation within the next thirty years, there will be added to the productive area in this region 60,000,000 acres, with state and railroad lands to the possible extent of 20,000,000 acres in addition. This will fall so far short of the requirements of our own population that it is necessary to seek other possible additions to the cultivable area.
>
> Not for the purpose of growing wheat, but under the influence of those generally higher prices which any considerable and long-continued increase in the price of wheat would bring about by reducing the acreage in other products, the South might conceivably add to her productive area as much as 30,000,000 acres. Ten million acres might be added on the Pacific coast and 3,000,000 acres in the arid region. This would make the gross addition 123,000,000 acres, against which must be set those continual withdrawals of land from agricultural uses which not even a high degree of agricultural prosperity would entirely prevent. Assuming the annual rate of diversion to be diminished by one-half, the loss during the next thirty years would amount to about 15,000,000 acres, making the net increase 108,000,000 acres.
>
> This will constitute an enormous addition to the productive capacity of the farms of the country, and one, the contemplation of which, aside from the question of consumption, might well appal our much-discouraged farmers. Considered, however, in the light of the requirements of a population of 130,000,000 the figures assume an entirely different aspect. On the basis of our present actual consumption as a people, to the entire exclusion of our export trade, the country will require by the year 1931 the following additional acreage: For wheat, 13,500,000 acres; for maize, 66,000,000 acres; for oats, 23,700,000 acres; for the minor cereals, 10,000,000 acres, and for hay, 40,500,000 acres, a total of 153,700,000 acres, without making any provision for the proportionately increased consumption of vegetables, fruits, and other products. Instead, therefore, of the probably largely increased acreage, bringing down prices, or proving unprofitable to the farmers, there will be a deficiency of at least 50,000,000 acres. Indeed, it will be more than this, since it can not be supposed for a moment that the unimproved lands left to the last are anything like equal in

---

[a] The Wheat Problem, p. 219 et seq.

natural fertility to those first selected for cultivation. On the other side of the account, however, we have to place whatever increase in yield per acre may be brought about by improved methods of farming. But whatever agricultural science may be able to do in this direction within the next thirty years, up to the present time it has only succeeded in arresting that decline in the rate of production with which we have been continually threatened. * * *

It must be borne in mind that it is only to a very small extent indeed that scientific methods have as yet been employed in the growing of field crops. It is unquestionably to the laboratory that we shall have to look for relief, except in so far as it may be afforded by the Government's undertaking the construction of storage reservoirs in the arid region that might reclaim not to exceed 71,500,000 acres, less whatever small area might in the meantime have been brought under cultivation in that region through private enterprise. * * *

The cultivation of wheat at the expense of other necessary crops will, however, be held in check by two very powerful influences. The first will arise from the fact that a reduction of the acreage under any product of general use below the actual requirements of the country will instantly—perhaps even prospectively—affect the price of that product, possibly in a proportion even greater than that by which its acreage is diminished, and may even be sufficient to constitute it a competitor with wheat on equal terms for the farmer's favor. The second check will be found in the fact that the American farmer, north, south, east, and west, has at last fully awakened to the safety, stability, and, in the long run, increased profit resulting from a judiciously diversified system of farming. The one-crop system has passed away, never to return, and before wheat can be extensively cultivated at the expense of other products it will not only have to command what would appear to us as an excessively high price, and afford a reasonable assurance of its continuing to do so, but would have to do this without affecting to any considerable extent the price of other products.

* * * * * * *

To discuss the extent to which under conceivable conditions the United States may, notwithstanding this somewhat dubious outlook, still continue to contribute to the food supply of other nations, would be little more than speculation. It is sufficient for the writer's present purpose to have called attention to the enormous prospective increase in the requirements of our own population, and to some of the changes in the agricultural situation which such increase will involve.

This discussion of the subject is quite in accord with the general view taken by Mr. Crookes and a number of others who have forecasted the situation, but the difficulty of making reliable estimates of food production and acreage is too apparent to need further discussion. The same is true regarding the acreage and production of foreign countries, some of which, even in the original home of the wheat plant, are producing only about 9 bushels per acre on the average, as indicated in the following table:[a]

Average yield of wheat per acre in—	Bushels
Denmark	41.8
United Kingdom	29.1
New Zealand	25.5
Norway	25.1
Germany	23.2
Belgium	21.5
Holland	21.5
France	19.4
Hungary	18.6
Roumania	18.5
Austria	16.3
Poland	16.2
Canada	15.5
Argentina	13.0
Italy	12.1
United States (mean)	12.0

---

[a] The Wheat Problem, p. 244.

Average yield of wheat per acre in—	Bushels.
India	9.2
Russia in Europe	8.6
Algeria	7.5
South Australia	7.0
Australasia	6.8

The average acreage devoted to wheat in the United States from 1866 to 1907 has gradually increased, slightly fluctuating from year to year through various causes, especially the price of wheat, the price of competing crops, etc. At the close of the civil war, in 1866, there were 15,424,496 acres devoted to wheat, with an average yield of 9.9 bushels and an average farm price of a little over $1.52 per bushel, 12,646,941 bushels of this crop being exported. In 1880 the acreage had increased to 37,986,717, with an average yield of 13.1 bushels and a farm price of a little over 95 cents, 186,321,514 bushels being exported. Up to 1901 the average fluctuated a little above and a little below the 37,000,000-acre point, reaching in 1901 49,895,514 acres, with an average yield of 15 bushels and an average farm price of 62.4 cents, with an export of 234,772,516 bushels. In 1902 the acreage dropped off something over 3,000,000 acres, and in 1903 it came back again to 49,464,967 acres, with an average yield of 12.9 bushels and an average farm price of 69.5 cents, and with an export of 120,727,613 bushels. In 1904, 1905, 1906, and 1907 the acreage has been between 44,000,000 and 47,000,000, with an average yield ranging between 12.9 and 15.5 bushels and a farm price ranging between 66 and 92 cents, the high prices running up as high as $1.13 in the year 1904 and $1.06 in 1906. The exports since 1903 have fallen off considerably. In 1903 the export was 120,727,613 bushels and in 1904 it was 44,112,810. This was coincident with the rust epidemic. In 1905 the exports amounted to 97,609,007 bushels; in 1906, 146,700,425 bushels; and for 1907 the figures were 163,043,669.[a] There is no positive evidence, therefore, from the figures available of any falling off in the ability of our farmers to meet the demand for home consumption of wheat and still supply a large amount for export.

I have already referred incidentally to the difficulty of determining the potential wheat-producing power of the land not now in farms, and of the uncultivated area in farms. As a further illustration of the difficulty of determining this, it is simply necessary to point out that most investigators, including Crookes and Hyde, up to ten years ago, figured that the area west of the one hundredth meridian was practically available only for grazing, with the exception of only a small per cent available for irrigation. Probably not more than 5, or at the most 10, per cent of the arable land west of the one hundredth meridian is considered available for irrigation, owing to the scarcity of water. Even this, however, is based upon the present wasteful methods of using water, and is subject to considerable revision when conditions of farming are such as to warrant subirrigation methods, which are now used in many localities with a saving of over 50 per cent of water. The irrigation ditches are now most of them not cemented or properly silted, so that there is a great waste by seepage. The water, furthermore, is exposed to evaporation, by which large quantities are lost. There are many methods that might be practically devised for using water more economically than at present, but, leaving the question of irrigated agriculture aside, the Great Plains area, which has not been considered as a potential feature in wheat production, is a territory over 300 miles wide and 1,000 miles long, and, on a most conservative estimate, contains 50 per cent of land which could be devoted to wheat culture, and, as a result of careful tests made by the Department of Agriculture, state experiment stations, and practical farmers it has been shown that, by the use of drought-resistant varieties of wheat and by the employment of cultural methods which conserve the natural rainfall, at least 96,000,000 acres of this land could be made to produce an average yield of 15 bushels per acre annually under the ordinary methods of culture now practiced by the best farmers of that region.

---

[a] Figures of Bureau Statistics, U. S. Dept. Agr.; subject to slight change by Dept. Com. and Lab.

The possibilities of increasing the wheat yield in the present well-established wheat areas have hardly been considered. As will be shown later, a very large number of varieties are now grown, many of them not well adapted to the conditions of soil and climate under which they are cultivated. An average increased yield of 5 bushels to the acre could be secured simply by putting into the hands of the farmers better adapted strains for their particular conditions. This is now rapidly taking place.

A study of the statistics of yield for the different wheat areas of the United States shows a gradual upward tendency for the United States as a whole for ten-year periods. Representing the average yield of the forty years from 1867 to 1906 by 100, the relative average yield per acre in each decade was as follows: 1867–1876, 94; 1877–1886, 98; 1887–1896, 100; 1897–1906, 108. The actual yields for States and periods are shown in the table of ten-year average yields, herewith appended.

According to investigations made by this department and published in Bulletin No. 24 of the Division of Vegetable Physiology and Pathology, "The Basis for the Improvement of American Wheats," 1900, as a foundation for rational wheat improvement, a knowledge is required, first, of the characteristics and needs of different wheat districts, and, second, of the characteristic qualities of the natural groups of wheat. On the basis of conditions of soil and climate and the nature of the varieties adapted to these conditions, the United States may be considered to be divided into eight wheat districts, as follows: (1) Soft wheat district, including mainly the Middle and New England States; (2) the semihard winter wheat district, including Ohio, Indiana, Illinois, Michigan, and a small part of Wisconsin; (3) the southern wheat district, including approximately the Southern States; (4) the hard spring wheat district, covering the northern portion of the States of the plains; (5) the hard winter wheat district, covering the central portion of the States of the plains; (6) the durum wheat district, covering the western portion of the States of the plains; (7) the irrigated wheat district, including approximately the Rocky Mountain and Basin States; and (8) the white wheat district, including the Pacific Coast States.

Certain general needs, such as early maturity, greater yielding power, and better adapted varieties, are common to all these districts and must be kept constantly in mind in connection with all efforts made to improve varieties. Other characteristics and needs are more special and are stated herewith under headings of the different districts:

Soft wheat district:
- (*a*) Present average yield per acre, about 14⅔ bushels.
- (*b*) Chief varieties now grown: Fultz, Fulcaster, Early Genesee Giant, Mediterranean, Early Red Clawson, Longberry, Jones's Winter Fife, Red Wonder, Gold Coin, Bluestem, Dietz, Red Cross.
- (*c*) Needs of the grower: Harder-grained, more glutinous varieties; hardier winter varieties for the most northern portions; early maturity; rust resistance.

Semihard winter wheat district:
- (*a*) Present average yield per acre, about 14 bushels.
- (*b*) Chief varieties now grown: Fultz, Poole, Rudy, Valley, Nigger, Dawson's Golden Chaff, Early Red Clawson.
- (*c*) Needs of the grower: Hardness of grain; rust resistance; hardy winter varieties.

Southern wheat district:
- (*a*) Present average yield per acre, about 9⅔ bushels.
- (*b*) Chief varieties at present grown: Fultz, Fulcaster, Red May, Rice, Everett's High Grade, Boughton, Currell's Prolific, Purple Straw.
- (*c*) Needs of the grower: Rust resistance; early maturity; resistance to late spring frosts; stiffness of straw.

Hard spring wheat district:
- (*a*) Present average yield per acre, about 14 bushels.
- (*b*) Chief varieties at present grown: Scotch Fife, Bluestem, Wellman's Fife, Velvet Chaff Spring.
- (*c*) Needs of the grower: Early maturity; rust resistance, drought resistance; hardy winter varieties.

Hard winter wheat district:
- (*a*) Present average yield per acre, about 14 bushels.
- (*b*) Chief varieties at present grown: Turkey, Fulcaster, Kharkof, Zimmerman, Fultz.
- (*c*) Needs of the grower: Drought resistance; early maturity.

Durum wheat district:
- (*a*) Present average yield per acre, 11¼ bushels.
- (*b*) Chief varieties at present grown: Mediterranean, Nicaragua, Fulcaster, Turkey, Kubanka (in north).
- (*c*) Needs of the grower: Durum varieties for southern district; drought resistance; rust resistance; early maturity.

Irrigated wheat district:
- (*a*) Present average yield per acre, about 21 bushels.
- (*b*) Chief varieties at present grown: Sonora, Taos, Turkey, Little Club, Defiance, Kharkof, Kubanka.
- (*c*) Needs of the grower: Increase of the gluten content; early maturity.

White wheat district:
- (*a*) Present average yield per acre, about 15 bushels.
- (*b*) Chief varieties at present grown: Australian, California Club, Sonora, White Winter, Foise, Palouse Bluestem, Palouse Red Chaff, Oregon Red Chaff, Little Club.
- (*c*) Needs of the grower: Early maturity; nonshattering varieties; hardy winter varieties in the colder portions.

Attention has already been called to the eight principal groups of our cultivated wheats. The special characteristics of these groups of wheats that are of prime importance in the work of wheat breeding are here given:[a]

1. Common bread wheat group:
- (*a*) Excellence of gluten content for bread making.
- (*b*) Excellence of certain varieties for cracker making.
- (*c*) Yielding power of certain sorts.
- (*d*) Rust resistance (in some varieties).
- (*e*) Winter hardiness of certain varieties.
- (*f*) Resistance to drought of certain varieties.
- (*g*) Early maturity (in some varieties).

---

[a] Bull. No. 24, Div. Veg. Phys. and Path., U. S. Dept. Agr., 1900, pp. 79-83.

2. Club or square-head group:
    - (a) Great yielding power.
    - (b) Stiffness of straw.
    - (c) Freedom from shattering.
    - (d) Early maturity (in some varieties).
    - (e) Drought resistance (in some varieties).
    - (f) Excellence of certain sorts for making crackers and breakfast foods.
3. Poulard group:
    - (a) Excellence of certain varieties for making macaroni.
    - (b) Resistance to orange leaf-rust.
    - (c) Resistance to drought.
    - (d) Stiffness of straw.
4. Durum group:
    - (a) Excellence of gluten content for making macaroni and other pastes.
    - (b) Resistance to drought.
    - (c) Resistance to orange leaf-rust.
5. Polish wheat group:
    - (a) Quality of gluten content for making macaroni.
    - (b) Resistance to drought.
    - (c) Resistance to orange leaf-rust.
6. Spelt group:
    - Desirable qualities—
        - (a) Ability to hold the grain in the head.
        - (b) Constancy in fertility.
        - (c) Hardiness of certain winter sorts.
    - Undesirable qualities—
        - (d) Brittleness of the head.
        - (e) Rust liability.
7. Emmer group:
    - Desirable qualities—
        - (a) Ability to hold the grain in the head.
        - (b) Drought resistance.
        - (c) Resistance to orange leaf-rust.
    - Undesirable qualities—
        - (d) Brittleness of the head.
        - (e) Adaptability only for spring sowing, as a rule.
8. Einkorn group:
    - Desirable qualities—
        - (a) Ability to hold the grain in the head.
        - (b) Resistance to orange leaf-rust.
        - (c) Hardiness.
        - (d) Resistance to drought.
        - (e) Stiffness of straw.
    - Undesirable quality—
        - (f) Brittleness of the head.

Wheats may also be grouped geographically. On this basis groups of varieties having certain special qualities are located approximately as follows:

- (a) Starchy white wheats: Pacific Coast and Rocky Mountain States, Chile, Turkestan, Australia, and India.
- (b) Amber or reddish grained wheats, also starchy: Eastern States, western and northern Europe, India, Japan, and Australia.
- (c) Excellence of gluten content for making the best bread: Northern and Central States of the Plains, Canada, eastern and southern Russia, Hungary, Roumania, and southern Argentina.
- (d) Resistance to orange leaf rust: Southern Russia, Mediterranean and Black Sea regions, and Australia.
- (e) Excellence of gluten content for making macaroni: Southern Russia, Algeria, and the Mediterranean region in general.
- (f) Stiffness of straw preventing lodging: Pacific Coast States, Japan, Turkestan, Mediterranean region, and Australia.
- (g) Yielding power (at least in proportion to size of head): Pacific Coast States, Chile, and Turkestan.
- (h) Nonshattering varieties: Pacific Coast States, Chile, Turkestan, Germany (spelts), and East Russia (emmers).
- (i) Constancy in fertility: Germany (spelts) and southern Europe.
- (j) Early maturity: Japan, Australia, and India.
- (k) Resistance to drought and heat: East and South Russia, Kirghiz steppes, Turkestan, and southern Mediterranean region.

(*l*) Resistance to drought and cold: East Russia.

Of the many wheat introductions made into this country in the past, the following are among those of the greatest moment, and which have completely revolutionized the wheat industry in places:

(*a*) Mediterranean, introduced first in 1819.
(*b*) Fife wheats, introduced first into Canada and then into the northern States of the Plains.
(*c*) Turkey wheat, first introduced into Kansas about twenty-five years ago from Taurida, in Russia.
(*d*) The California Club, Australian, and Sonora, introduced into the Pacific Coast States.

Field experiments of the department have shown that in the common bread-wheat group there is a very close constant relation between the autumn condition of the young plant on the one hand and winter hardiness and quality of grain on the other.

Wheat is very susceptible to changes of environment, but especially in regard to color, hardiness, and chemical composition of the grain.

In general, regions possessing black prairie soils and characterized by violent climatic extremes, especially extremes of heat and drought, produce wheats that are hardiest, have the hardest grains, and are the best in quantity and quality of gluten content.

Considering all qualities, the best wheats of the world are of Russian origin, coming particularly from eastern and southern Russia, the Kirghiz steppes, and Turkestan. Of Russian varieties so far known, the following are among the best, if not the very best:

Arnautka, Ghirka Spring, Crimean, Mennonite, Yx, Kubanka, Ghirka Winter, Buivola, Kubanka Red Winter, Chernokoloska, Turkey, Russian, Sarui-bug-dai, Beloturka.

The earliest ripening wheats are often dwarfed. The following varieties are among the best of this class:

Yemide, Onigara, Shiro-Yemidashi, Kintama, Kathia, Roseworthy, Early Baart, Early Japanese, Japanese No. 2, Nashi, Allora Spring, Steinwedel, King's Jubilee.

The following varieties are among the best known of the durum and poulard groups:

Arnautka, Kubanka, Beloturka, Chernokoloska, Medeah, Sarui-bug-dai, Cretan, Galland's Hybrid, El Safra, Petanielle noire de Nice, Volo, Missogen, Atalanti, Nicaragua.

Common bread wheats can not be depended upon to resist rust, but the best in this regard are probably the following:

Turkey, Pringle's Defiance, Rieti, Pringle's No. 5, Nashi, Saskatchewan Fife, Theiss, Bellevue Talavera, Arnold's Hybrid, Crimean, Oregon Club, Odessa, Velvet Bluestem, Sonora, Prolifero, Mediterranean, Deitz Longberry, and Mennonite.

Einkorns resist leaf-rust completely, and emmers resist it to a high degree.

Some of the very hardiest winter varieties so far tried in this country are:

Turkey, Yx, Crimean, Ghirka Winter, Bearded Winter.

Club wheats are usually soft-grained and tender sorts, adapted only to mild climates like that of California. Among the best of this group are:

Little Club, California Club, Herisson barbu, Palouse Red Chaff, Chili Club, Sicilian Red Square-head, Herisson sans barbes.

Some of the most popular and valuable wheats of our country have been produced by simple selection, though in some cases the indications are strong that they were originally the result of natural crossing. The best known of such varieties are:

Fultz, Clawson, Gold Coin, Rudy, Wellman's Fife, Currell's Prolific.

Selection plays far the most important part in wheat breeding, and necessitates on the part of the experimenter a thorough knowledge of varieties and their relations to each other and to their environment.

Simple selection of individuals, however, for the improvement of the same variety, can and should be practiced on every farm. Very little extra time or trouble is required, but the gain is great.

Among the most valuable wheats of the United States that have been produced through hybridization are the following:

Fulcaster, Gypsum, Improved Fife, Quartz, Ruby, Jones's Winter Fife, Early Genesee Giant, Early Arcadian, Pringle's Defiance, Pringle's No. 5, Hornblende, Felspar, Blount's No. 10, Diamond Grit, Early Red Clawson, Early White Leader.

For the most complete success in wheat improvement through hybridization it is necessary to practice composite crossing with parents selected from widely different wheat groups.

The wheat plant is so closely self-fertilized in nature that the practice of composite crossing produces some most interesting and remarkable results. There is apparently no end to the variations exhibited by the sporting progeny in such cases, and, accompanied by discriminating selection, the possibilities of wheat improvement in this way are practically unlimited.

Studying along the lines here laid down, the Department of Agriculture and a number of the state experiment stations have made great progress in improving the varieties of wheat cultivated in these various regions. It has been possible to secure acclimatized strains in various parts of the Old World wheat areas where, as the result of centuries of culture under severe limiting conditions, strains and varieties have been gradually developed through natural and artificial selection very resistant to those conditions. Thus we find very cold and drought resistant durums, like the Kubanka and Arnautka, adapted to the cold dry northern area and other strains developed in northern Africa and the Mediterranean region adapted to the hot dry situations of Texas and Oklahoma. The hard winter wheats of the Great Plains and the Mississippi Valley are inferior in cold-resisting power and yielding power to very closely related strains which have been secured in Russia. As a result of careful explorations of European Russia, including the Caucasus and a portion of the Kirghiz Steppes, as well as Hungary, Roumania, and other portions of Europe, a very large number of promising strains of different varieties were secured, which were tested in connection with a large number of strains secured in this country, making altogether about 1,000 varieties.

The Kharkof strain of the so-called Turkey wheat has carried the range of winter wheat culture from southern Nebraska into southern North Dakota, a distance something over 400 miles, and has carried the western range of winter wheat culture beyond the one-hundredth meridian. This strain is also proving valuable in Iowa, Minnesota, Wisconsin, and Illinois. The winter wheats, besides being more certain in yield, average about 5 bushels more than spring wheats.

The rust-resisting qualities of some of the durum wheats have been bred into the Bluestem strains, making them very much more valuable for culture in the northern Mississippi Valley, but these have not yet been distributed by the department.

The great problem in the South is good varieties of wheat, better adapted for growth under the warmer conditions, and which are rust-resistant. While very little has yet been done along this line, it is undoubtedly possible by the introduction of strains adapted to southern conditions and having greater rust resistance to very greatly increase the now very low yield of the Southern States. Several investigators have from time to time pointed out that the highest yield of any strain of a crop is usually produced near the northern limit of its production. This is true so far as any given strain or variety is concerned, but there is no reason why the Southern States should not be the northern limit of production for certain varieties of wheat, the same as northern Canada is the limit for other varieties. This point has been overlooked in much of the discussion upon the potential wheat-producing power of the Southern States. It is the opinion of those who have given this question long and careful study that the average wheat production of the United States as a whole could easily be doubled by the use of better varieties and better cultural methods. How rapidly changes of this kind will take place will depend upon how rapidly information can be diffused among the farmers. If dependence is placed upon the distribution of information through publications, the change will be very slow, but if the information is carried to the people directly, as is being done by the Department of Agriculture in its farm demonstration in the South, it is believed that even a few years will suffice to get the people to use better methods. It will then be simply a question of how rapidly the scientists can improve the strains and get them into condition for distribution and general use.

The first steps must necessarily be those more fundamental features of general farm practice—the diversification of crops, building up of the humus of the soil by the use of barnyard manure and green crops turned under, more attention given to the selection of even ordinary varieties of seed, etc. As soon as the farmer makes the first steps in this direction, he is able to appreciate and make better use of more highly selected strains and more complicated methods.

The breeding work is actively in progress by many of the state stations, as well as the department experts, and it is probable that the progress of the breeder will fully keep pace with the development of the farmer and that the United States can be depended upon, not only to feed its own rapidly increasing population, with the same relative proportion of wheat that they now use, but that it will have a large and ever increasing quantity for export.

So far as the effect of soil conditions on wheat yield is concerned, it has been proved beyond question that, where wheat is grown continuously on the same soil without the addition of organic matter, the productive power of the soil is reduced. It has been shown beyond any question that the continuous growth of cultivated crops is even more destructive of soil humus than the continuous growth of grain crops. The stirring of the soil in the process of cultivation stimulates the action of the nitrifying and ammonifying bacteria, which convert the organic nitrogen of the soil into available form, so that it is either taken out by the crops or is leached away.

The influence of the different systems of farming on the chemical and physical properties of the soil is well illustrated by the following facts secured at the Minnesota Experiment Station, and which are typical of the results secured by practically all other investigators in this field:[a]

Influence of different systems of farming on the chemical and physical properties of soils.

Character of soil.	Weight per cubic foot.	Humus.	Nitrogen.	Phosphoric acid combined with humus.	Water-holding capacity.

[a] Humus in Its Relation to Soil Fertility, by Harry Snyder, Yearbook, U. S. Dept. Agr., 1895, p. 141.

Soils Nos. 1 and 2 are from two adjoining farms, and originally had practically the same crop-producing power. No. 1 has received regular and liberal dressings of manure, and has produced wheat, corn, oats, timothy, and clover in rotation. There has been no apparent decline in fertility. No. 2 has been under continuous grain cultivation and has never received any farm manure or other humus-forming materials. During the first few years heavy crops of wheat were raised, but during the past few years the yield has been very low, especially in dry seasons. The land has been reduced in wheat-producing power from 25 to 8 bushels per acre.

The main difference between the two soils at the present time is in the amount of humus and nitrogen and phosphoric acid.

Soils Nos. 3 and 4 are from the same farm. No. 3 has been cropped forty-two years, timothy and clover, wheat, oats, and corn having been raised in rotation. Every five years the land has received 10 tons of stable manure per acre. No. 4 has been cropped only thirty-five years, producing mainly wheat, oats, and corn, with an occasional crop of timothy. It has not been cropped continuously to one crop, neither has it been under a regular system of rotation. The soil which has been cropped forty-two years shows more humus and nitrogen than the one which has been cropped thirty-five years.

The earlier results secured in these experiments in Minnesota have been confirmed by all of the later investigations. In Bulletin No. 109 of the Minnesota Experiment Station, issued in June, 1908, pages 330 to 334, the results are summarized as follows:

1. Continued cropping of soils to grains only, without any system of rotation, or other treatment, is telling severely upon the original stock of half-decomposed animal and vegetable matter and nitrogen. Soils which have produced grain crops exclusively for ten or fifteen years contain less humus and nitrogen than adjoining soils that have never been plowed.

2. Soils which have been cropped until the organic matter and humus have been materially decreased retain less water and dry out more readily than when there is a larger amount of organic matter present in the soil.

3. Soils which are rich in humus contain a larger amount of phosphates associted with them in available forms than soils that are poor in humus.

4. Soils which are rich in humus and organic matter produce a larger amount of carbon dioxide which acts as a solvent upon the soil particles and aids the roots in procuring food.

5. One-half of a sandy knoll, heavily manured with well-rotted manure, contained nearly a quarter more water during a six weeks' drought than the other half that received no manure.

6. The supply of organic matter in the soil must be maintained, because it takes such an important part, indirectly, in keeping up the fertility. A good system of rotation, including sod crops and well-prepared farm manures, will do this, and will avoid the introduction and use of commercial fertilizers which are now costing the farmers of the United States over $80,000,000 annually. It will not do to wait until this question forces itself upon us.

7. A rotation of crops will soon be necessary on account of the peculiar composition of some of the soils and corresponding subsoils, especially those where the surface soils are richer in phosphates and nitrogen while the subsoils are richer in potash and lime. By means of rotation the full benefit of the strong points of both the top soil and the subsoil will be secured.

The decay of the humus and liberation of its nitrogen is only one of many changes that has taken place. Loss of the element nitrogen can not be said to be the only cause of decline in fertility, as field experiments with fertilizers on old grain lands show that nitrogen alone, when added to the soil, fails to entirely restore the fertility. In addition to the decay of the humus and loss of nitrogen, the mineral elements of plant food have undergone changes in combination, the soils have become lighter in color and otherwise modified in physical properties. * * *

Commercial fertilizers should not be used indiscriminately on old soils with a view of securing large yields, and it is not feasible by their use alone to economically restore the fertility to soils that have been impoverished by exclusive cropping to small grains. Commercial fertilizers are of great value when judiciously employed in a rotation and for encouraging the growth of legumes, as clover, so as to add nitrogen to the soil from atmospheric sources. * * * Commercial fertilizers can not take the place of farm manures or crop residues, particularly those from clover and timothy, for permanently improving the soil, but they aid in the production of some crops and often assist a crop, as clover, which in turn is beneficial in adding nitrogen and humus to the soil.

* * * * * * *

A rotation of grain crops alone, without the production of clover or a grass crop, was found not to be sufficient to conserve the nitrogen content of the soil, even where farm manures were used. A rotation of crops, in order to be effectual, must contain clover as one of the essential parts.

* * * * * * *

The beneficial action of a clover sod, grass crop residues, and farm manures upon the soil is not alone confined to supplying nitrogen and humus-forming materials, but chemical, bacteriological, and physical changes are also promoted in the soil. * * *

The indiscriminate practice of bare summer fallowing has been another cause of loss of the soil's nitrogen and humus. * * * Experiments show that when summer fallowing is practiced five times more nitrogen is rendered soluble and available than is required for the succeeding crop; and the soluble nitrogen that is not utilized as plant food is readily lost. * * *

On most western farms it is more economical at the present time to make the reserve mineral matter available as plant food than to purchase new stores. In many soils there is a large amount which is not in the most available forms, but is capable of being made so by cultivation.

As a general result of the cropping system it was found that any system which provided for the maintenance of a supply of vegetable matter in the soil, either by manuring or by the growing of pasture or meadow crops, has given profitable returns. A standard five-year rotation—first year, corn, receiving 8 tons of manure per acre; second year, wheat; third and fourth years, meadow; fifth year, oats—has given an average gross income per year for the State of Minnesota, based on average farm prices, of $14.08. The cost of production, including $3.50 land rental, is $9.05, leaving the net annual income $5.03 per acre.

The plots which have grown cultivated crops, such as corn, potatoes, and mangels, continuously without manure, have given poorer returns than have the plots which have grown grain continuously without manure.

A four-year rotation—millet, barley, corn, and oats—gave no better returns than did the plot on which wheat was grown continuously.

The yields of wheat in the standard five-year rotations have ranged between 20 and 30 bushels, some seasons and rotations giving as high as 35 bushels, while the average for the State is about 13 bushels.

Emmer.—Before closing the discussion of wheats attention should be called to emmer, which is destined to be an exceedingly important dry-land crop for high altitudes and poor soils. The following is abstracted from Farmers' Bulletin 139:

Emmer is a species of wheat, *Triticum dicoccum*, probably derived in prehistoric times in southeastern Europe from a still simpler species, *T. monococcum*. It is often confused with another similar species, *T. spelta*, and is thus incorrectly called "spelt." The grain is somewhat similar to that of spelt, but is usually harder, more compressed at the sides, and redder. Emmer is a much more hardy plant than spelt in every way. It resists drought and attacks of leaf rust to a great degree. Fall-sown varieties are also quite winter-hardy. It will produce a fair crop under almost any condition of soil and climate, but thrives best in a dry prairie region with hot summers, where it gives excellent yields, 30–60 bushels. The grain is largely cultivated in the upper Volga region of Russia, where the climatic conditions are more severe than in our northern Great Plains region. Excellent varieties are also grown in the North Caucasus, in Germany, Switzerland, France, Italy, Servia, Abyssinia, northern India, China, and Thibet. Only a few varieties, however, have yet been introduced and tested in this country. From the tests thus far made the Russian white-chaff varieties give excellent results in the northern plains district, and the black winter varieties give good results further South. With the introduction and acclimatization of new varieties this grain promises to take an important place in our agriculture, replacing oats and barley under conditions too severe for those crops and being about equal to them as stock food.

OATS.

A statement [a] of the status of oat culture in the United States has been especially prepared by Mr. C. W. Warburton and is submitted herewith.

The improvement and adaptation of varieties and the greatly increased yields resulting from such work are fully as great as in the case of corn and wheat.

Although oats exceed in nutrition value our other cereals, probably less care has been given to their culture than to any other important crop; oats are usually grown also on the poorest land. Their great value as feed, especially for horses, results in their culture even at a loss, so far as their market value is concerned. The acreage devoted to oats doubled from 1879 to 1887 and increased from 1887 to 1900 from 25,920,906 acres to over 27,000,000, with a corresponding increase in yield. In 1907 the acreage was 31,837,000, but on account of rust, smut, insect pests, and unfavorable weather conditions, the yield fluctuated considerably in various years and localities. The loss from smut alone is estimated at not less than 4 per cent of the crop, or on an average of about 34,000,000 bushels. This can be easily prevented at very small cost. Rust is more difficult to control, except through the use of resistant varieties. The loss caused is fully as great as that caused by smut. Selection and adaptation of varieties, with better rotation systems, will greatly increase the yield per acre as soon as there is demand for it. At current prices the acreage will probably remain about as at present, with a tendency to decrease as average yields increase as the result of better systems of rotation. The net profits will at the same time considerably increase.

BARLEY.

Barley is successfuly cultivated under a wider range of climatic and soil conditions than any other cereal, though it reaches its best development in warm, dry climates. Barley belongs to the same tribe as wheat and rye. The chemical composition of the grain, after taking off the hull, is almost identical with wheat. It is one of the oldest of cultivated crops. Down to the sixteenth century it was the chief bread plant of Europe, but since that time it has given way to wheat. Its chief use in America is as food for domestic animals and for malting purposes. In 1850 New York produced about 69.4 per cent of the barley grown in the United States. The North Atlantic division produced 81 per cent. In 1900 the center of production was the northern Missouri Valley, in Iowa and South Dakota. Nine States now produce about 91 per cent of the total yield, viz., California, Minnesota, Wisconsin, Iowa, South Dakota, North Dakota, Washington, New York, and Nebraska,[b] the first four producing three-fourths of the total crop. The world's production of barley for the past five years, 1903 to 1907, has been a little over 1,200,000,000 bushels. The acreage has gradually increased in the United States from 492,532 in 1866 to 1,131,217 in 1867, reaching 2,272,103 in 1882, 3,220,834 in 1889, falling a little below 3,000,000 from 1896 to 1900, then increasing to 4,295,744 in 1901, 5,145,878 in 1904, and 6,448,000 in 1907.

---

[a] See statement on Oat Crop of the United States prepared by C. W. Warburton for this report.

[b] See Cereals in America, by Thomas F. Hunt.

The yield per acre has fluctuated between 19.2 and 29 bushels, averaging, from 1867 to 1876, 22.8 bushels; from 1877 to 1886, 22.4 bushels; from 1887 to 1896, 22.7 bushels; and from 1897 to 1906, 25.5 bushels.

The farm value has been gradually declining, but it increased in 1907 to 66.6 cents, the highest since 1881.

Varieties.—There are two well marked types of barley, the six-rowed and the two-rowed, both of very ancient cultivation and possibly representing separate species. An intermediate form (*Hordeum vulgare L.*) is the common four-rowed barley. The two-rowed varieties of the Hanna and Chevalier type appear to be better adapted to the drier Northwest; while the six-rowed varieties, like Oderbrucker and Odessa, do better in the moister regions. North of the forty-third parallel it is necessary to sow in the spring, but south of this line fall sowing is rapidly coming into favor, especially since 1903, when the Department of Agriculture began to demonstrate the superior value of the winter strains, which yield on an average 25 to 30 per cent more than the spring sorts south of the forty-third parallel. The principal reason is that the fall-sown grain ripens before the hot summer weather arrives. Drilled winter barley in Indiana, Illinois, and Ohio has stood the winter better than broadcasted barley, two-thirds of the loss from winter killing being prevented by this method.

Several years ago the Department of Agriculture introduced a considerable number of hull-less and beardless barleys from the high plateaus of the Himalaya Mountains in Asia and distributed them through the Rocky Mountain States. Their success has been phenomenal. Their cultivation has been successfully carried up to nearly 9,000 feet, where they give valuable hay as well as grain. Large quantities are grown under irrigation in the mountain sections of Montana, Wyoming, and Colorado. They have also been found to be well adapted to the semiarid area of the Great Plains, proving to be one of the best dry-land crops. Like wheat, oats, and corn, and, in fact, most other crops, the barleys do best in soils rich in humus and decaying organic matter. They decline rapidly in yield if the humus and organic matter is not maintained, being more sensitive than other cereals in this respect. In the rich tule lands of California a yield of 80 to 90 bushels per acre is often secured, and under favorable conditions nearly as high yields are often secured in the northern Mississippi Valley. Under average conditions, however, 35 to 40 bushels is considered a fair yield. This is from 10 to 15 bushels above the average for the last decade for the principal barley area and from 15 to 20 bushels above the average for the South. As better rotation methods and cultural methods generally come into use the average yield of this crop, like that of all others, gradually increases.

RYE.

The acreage of rye in the United States has fluctuated between one and a half million and two million acres from 1866 down to the present. The average yield per acre declined slightly down to the beginning of the last decade, during which there has been an average increase of 3 bushels per acre (13.6, 13.0, 12.9, 15.7). The farm value has fluctuated considerably, falling as low as 40.9 cents in 1896, ranging between 50 and 60 cents during the last ten years, reaching 68.8 cents in 1904 and 73.1 cents in 1907. The exports fluctuate greatly.

From the standpoint of its grain value, rye is the least profitable of our cereal crops. It is, however, adapted to very light, poor land, and will make a fair crop where other cereals, with the exception of emmer (sometimes erroneously called "spelt"), would fail. Like the other cereals, however, it responds to better soils or to fertilization.

On account of its great hardiness and its ability to grow on poor soils, it is largely used as a green manure crop.

There is a great demand for rye straw for paper and for other purposes, and, except where it is grown for green manure, it is grown principally for the straw. The grain makes a good flour for human food, but in this country it is not much used except for domestic animals and for brewing purposes.

The yield could be greatly increased, if desired, both by the use of better cultural methods and by selection of high-yielding strains.

RICE.

This is a cereal crop especially adapted to wet soils where other cereals will not grow. The genus *Oryza* is tropical, and there are a number of species of the genus growing wild in the Tropics of both hemispheres. A closely related genus, *Zizania*, is widely distributed in semitropical and northern countries. *Z. aquatica* occurs extensively in marshy places throughout North America and northeastern Asia. In North America it was extensively planted in marshes and used by the Indians as food. The southern wild form of the Gulf States, *Z. miliacea*, is used only for hay.

The cultivated rices originated in southern Asia in prehistoric times. There are five principal groups, corresponding possibly to species, indigenous to southern Asia, especially China. Like other cereals, there are a great number of varieties or strains adapted to a great variety of conditions, both upland and aquatic. One hundred and sixty-one varieties are recognized in Ceylon alone, and about 1,400 in China, India, and Japan. Only a few varieties have been introduced into culture in the United States, though about 800 are under test by the Department of Agriculture.

The principal areas in the United States devoted to rice are (1) the delta land and inland marshes of the South Atlantic States, (2) similar land along the Gulf coast and the southern Mississippi River, and (3) the prairie soil of southwestern Louisiana and southeastern Texas. The prairie rice culture is much like that of wheat or oats. The upland rices, however, are not as good in quality or as high yielding as those grown under irrigation, and, while it can be grown on any soil that will produce corn or cotton within the cotton belt, it will not compete with other grains on these soils as a rule. Where irrigation is practicable, as it is in some of the prairie regions of southwestern Louisiana and southeastern Texas, systems of irrigation and culture have been developed by which it is possible to use the same machinery as is used in cultivating wheat, thus greatly lessening the labor cost as compared to culture in swampy areas, which can not be drained sufficiently to permit the use of such machinery. The following table, taken in part from Farmers' Bulletin 110, shows the difference in labor cost for the United States as compared with other countries:

Number of acres one man can farm in rice, with wages, in different countries.[a]

Countries.	Acres.	Farm wages, in gold per year, with board.
Japan	½ to 2½	$10 to $18
China		8 to 12
Philippines		15 to 20
India	3	10 to 20
Siam	3	10 to 20
Egypt	4	15 to 30
Italy	5	40 to 60
Spain	5	40 to 60
United States:		
Carolinas	8	96 to 120
Mississippi Delta	10	120 to 144
Southwestern Louisiana and Texas	80	180 to 216

[a] Farmers' Bul. No. 110, p. 10. U. S. Dept. Agr., 1900.

The following table shows the acreage, production, and value of rice in the United States in 1907, by States:

Acreage, production, and value of rice in the United States in 1907, by States.

State.	Area.	Average yield per acre.	Production.	Average farm price December 1.	Farm value December 1.
	Acres.	*Bushels.*	*Bushels.*	*Cents.*	*Dollars.*
North Carolina	1,000	23.0	23,000	91	21,000
South Carolina	19,100	27.0	516,000	107	552,000
Georgia	2,400	34.0	81,000	105	85,000
Florida	2,300	30.0	69,000	110	76,000
Alabama	1,400	25.0	35,000	95	33,000
Mississippi	1,100	22.0	24,000	90	22,000
Louisiana	310,000	28.0	8,680,000	85	7,378,000
Texas	284,000	32.0	9,088,000	85	7,725,000
Arkansas	6,000	37.0	222,000	85	189,000
United States	627,300	29.9	18,738,000	85.8	16,081,000

The yields have been greatly reduced in the Carolinas by a disease known as "blast." It is believed that varieties resistant to the disease can be developed. The same disease has appeared in the rice areas of Louisiana and Texas, where it is already causing considerable trouble. The introduction by the Department of Agriculture of better milling and better yielding varieties, especially the Kiushu, greatly stimulated the culture of this cereal in the Louisiana and Texas prairies.

According to Knapp, there are about 10,000,000 acres of land in the five States bordering on the Gulf of Mexico well suited to rice cultivation. Only about 3,000,000 acres of this, however, can be irrigated and cultivated by machine methods. As rotation systems will be required in order to control weeds and keep up the humus supply, only about one-half of this would be devoted to rice in any one year. The present acreage devoted to rice, as shown in the table just cited, is 627,300, with an average production of 29.9 bushels, or 18,738,000 bushels. Besides this the United States annually imports over 120,000,000 pounds of rice. The amount has been gradually increasing, being over 200,000,000 pounds in 1906. It is evident, therefore, that the demand for rice is increasing. If the million and a half acres available for rice each year in the South should be put into this crop and the yield should be about the average of 10 barrels (162 pounds) per acre, the product would amount to 2,500,000,000 pounds of cleaned rice, nearly six times the amount of our present consumption. It is evident, therefore, that this food resource has great potential value and can fully keep up with the demand at remunerative prices. As Knapp[a] states in Farmers' Bulletin No. 110:

> The employment of machinery in the rice fields of the Southwest similar to that used in the great wheat fields of California and the Dakotas is revolutionizing the methods of cultivation and greatly reducing the cost. The American rice grower, employing higher-priced labor than any other rice grower of the world, will ultimately be able to market his crop at the least cost and the greatest profit. If, in addition, the same relative improvement can be secured in the rice itself, if varieties which yield from 80 to 90 per cent of head rice in the finished product can be successfully introduced, American rice growers will be able to command the highest prices for their product in the markets of the world. In view of the success in this direction of the Kiushu rice, experimentally introduced by the Department of Agriculture, more than 100 tons of this rice were ordered from Japan by Louisiana planters for the season of 1900.

SORGHUMS.[b]

All of the sorghums now in cultivation probably originated from a wild species native in tropical Africa.

The sorghums grown in this country may be separated into four groups—(1) the broom corns, (2) sorgo, or sweet sorghums, (3) kafirs, and (4) durras. The broom corns are grown only for their brush. The sweet sorghums are grown for forage and sirups, the kafirs for grain and forage, and the durras principally for grain. The last two groups are generally known as the nonsaccharine sorghums and are especially adapted to the hot, dry, or semiarid sections of the West and Southwest. All the varieties are very resistant to alkali. The durras are especially alkali and drought-resistant and adapted to higher altitudes. They are taller and less leafy than the kafirs. While the kafirs are most largely grown and have the widest adaptation, some of the improved strains of durra or milo are coming into prominence in the drier areas of the Great

---

[a] Rice Culture in the United States, by Dr. S. A. Knapp, Farmers' Bul. 110, U. S. Dept. Agr.

[b] See Farmers' Bul. 135, Sorghum Sirup Manufacture; 174, Broom Corn; 246, Saccharine Sorghums for Forage; 288, The Nonsaccharine Sorghums; 322, Milo as a Dry Land Grain Crop; and Cereals of America, by Hunt.

Plains, especially western Texas, New Mexico, Oklahoma, and Kansas.

The ordinary so-called dwarf milo obtainable in the market is the type usually grown, but on account of its lack of uniformity in height of seed heads and bending of the heads it is very difficult to handle by machinery. Improved strains, nonsuckering and uniform, with upright heads and light yellow seeds, have been developed and are being distributed by the Department of Agriculture. These are handled easily by the ordinary harvesting machinery and yield from 25 to 55 bushels of grain per acre. Its value for stock food is slightly less than that of corn, containing a slightly smaller percentage of protein and half the percentage of fat. In tropical countries, however, the sorghums are almost as largely used for human food as rice. In this country their use as human food is principally as griddle-cake flour.

The principal value of the sorghums to the United States lies in their adaptation to conditions where other grain and forage crops are more difficult to produce. The opportunities for improving and adapting the various strains are very great.

It is doubtful whether the sweet varieties can ever compete with sugar-cane and beets for sugar manufacture. They may prove, however, to be a valuable crop for the manufacture of denatured alcohol. As a soiling crop and for hay and silage mixed with legumes the sweet sorghums are superior to the nonsaccharine sorts, though the latter are now principally in use.

It is not a perfectly safe pasture plant on account of the prussic acid likely to develop in second-growth plants or plants which have been frosted or otherwise checked. Sorghum is, however, extensively used for pasture.

BUCKWHEAT.

Buckwheat belongs to the smart-weed family and is adapted to poor soils and short cold seasons. It grows wild on the banks of the river Amur in Manchuria, in Dahuria, and near Lake Baikal. It has long been cultivated in China, northern India, and in the Himalaya Mountains. The species came into central Europe in the middle ages through Tartary and Russia. It was early introduced into America and is quite extensively cultivated in New York, Pennsylvania, Michigan, Wisconsin, and Maine, these States producing four-fifths of the crop in 1899. The acreage and production have been about constant since 1870, when the acreage fell from a little over 1,000,000 to a little over 500,000. It reached 800,000 in 1880, and has fluctuated about this figure to date. The average yield, in bushels, per acre in the United States for 1866 was 21.8 bushels; in 1867, 17.4; for the decade 1868-1877, 17.4 bushels; for the decade 1878 to 1887, 14.1 bushels; 1888-1897, 16.2 bushels; 1898-1907, 17.8 bushels. The table[a] on the following page shows the acreage, production, and value of buckwheat in the United States in 1907, by States.

---

[a] Yearbook, U. S. Dept. Agr., 1907, p. 649.

Area and value of buckwheat in the United States in 1907.

State.	Area.	Average yield per acre.	Production.	Average farm price December 1.	Farm value December 1.
	Acres.	*Bushels.*	*Bushels.*	*Cents.*	*Dollars.*
Maine	23,000	28.0	644,000	65	419,00

Under favorable conditions, buckwheat will mature a crop of seed in from eight to ten weeks. It will grow at higher altitudes and farther north than any other grain crop. It is not affected by diseases or insects, but is very sensitive to heat and drought. The Japanese variety is the hardiest strain, which with Silver Hull and Common Gray are the types commonly grown in the United States. The flour is used principally for pancakes and as food for hens. Its average farm value is about $11 per acre.

IMPORTANCE OF CEREAL CROPS.

On account of the relatively important position that cereal crops have occupied in the past and always will occupy in the agriculture of the world they have been chiefly discussed individually. The comparative areas and value of cereals in the United States as compared with other field crops is shown in the following table compiled from the Twelfth Census by Hunt:[a]

Area and value of field crops in the United States in 1899.

	Area (acres).	Value of crops.	Value per acre.
Cereals	184,994,598	$1,484,231,038	$8.02
Hay and forage	61,691,166	487,125,685	7.90
Legumes for the seeds	1,964,634	28,308,228	14.41
Tubers	2,938,952	98,387,614	33.48
Roots	537,447	19,876,200	36.98
Sugar plants	855,995	51,367,685	60.01
Fibers	26,401,660	390,879,985	14.80
Stimulants	1,101,483	56,993,003	51.74

---

[a] The Cereals in America, by Thomas F. Hunt, p. 3.

Of the total area in hay and forage crops, 6.7 per cent was devoted to clover, 50.7 per cent to tame and cultivated grasses other than clover, 6.3 per cent to grains cut green for hay, 5.1 per cent to forage crops, 3.4 per cent to alfalfa, 2.8 per cent to millet and Hungarian grasses, and 25.1 per cent to wild, salt, and prairie grasses.

The acreage, production, and value of the eight cereals in 1899, and percentage of the total contributed by each, are shown in the following table, taken from the Twelfth Census:[a]

Grain.	Acres.	Bushels.	Value.	Per cent of total acreage.	Per cent of total yield.	Per cent of total value.
All cereals	184,994,588	4,434,698,746	$1,484,231,038	100.0	100.0	100.0
Corn	94,916,911	2,666,440,279	828,258,326	51.3	60.1	55.8
Wheat	52,588,574	658,534,252	369,945,320	28.4	14.8	24.9
Oats	29,539,698	943,389,375	217,098,584	16.0	21.3	14.6

Buckwheat	807,060	11,233,515	5,747,853	.4	.3	.4
Rice	351,344	4,728,710	7,891,613	.2	.1	.6
Kafir corn	266,513	5,169,113	1,367,040	.2	.1	.1

HAY AND FORAGE CROPS.

According to the last census, the total improved farm area in the United States in 1899 was 414,000,000 acres, of which nearly 290,000,000 acres were in crops of all kinds. The difference, approximately 125,000,000 acres, was probably devoted to pasture. This, in addition to the area utilized for cultivated grasses and forage crops, makes the area devoted to these classes of plants nearly 189,000,000 acres—approximately 4,000,000 acres greater than that devoted to all the cereal crops combined. A considerable portion of this land, now in wild grasses and pastures, has in some States formerly been cultivated to cereal and other crops and could now be utilized for that purpose, if necessary, or if such utilization were more profitable than their use for pasture. In some States a considerable portion of this land is mountainous or swampy and under present conditions would probably be utilized only for pasture and hay crops. The percentage of the land thus devoted to wild pasture and hay crops is shown in the census report and the statistics will therefore not be repeated here.

The largest increase in the utilization of this wild-grass land for cultivated grasses and forage has occurred in the West and in the South. In the South the increase is due largely to the fact that large areas which were formerly in many cases under cultivation have been allowed to run wild for long periods, but with the general agricultural progress of the South, the development of stock raising, and the diversification of crops, these lands are being utilized for cultivated hay and forage crops. The production per acre in the Southern States has increased faster than the acreage, which is the result of the use of better agricultural methods, especially the more general use of leguminous crops and fertilizers.

The rapid development of the use of unimproved grass lands for cultivated forage is coincident in nearly all the States with an increase in the live-stock interests, as shown by the census reports. The general summaries, showing the acreage and value of hay and forage crops, compared to the value and acreage of all crops, and the acreage of improved land, is here included to show the very great importance of the hay crops:[a]

[a] Data for Alaska and Hawaii included in totals for United States, but not in those for the 5 geographic divisions.

The hay and forage crops are made up of a very large number of both wild and cultivated species. On the ranges of the West, and to a considerable extent in the North Central States and the Southern States, wild grasses enter into the composition of the hay, even on lands that are under cultivation. There are about 3,500 known species of true grasses, divided into about 300 genera. Of this number there are in the United States 1,380 species (1,275 native and 105 introduced), divided among 165 genera. Scribner estimates that 38 of these grasses have earned a high reputation as hay grasses, 35 as pasture grasses, 14 as lawn grasses, and 24 as grasses for wet lands, 20 for embankments, and 19 for holding shifting sands, the same grass occasionally occurring in the different categories.

In the census returns the true grasses are listed as (1) wild, salt, and prairie grasses, the total acreage amounting to nearly one-fourth of all the acreage producing hay and forage; (2) the millet and Hungarian grasses, grown especially in the North Central and South Central divisions, but to some extent throughout the United States. The total area reported in this class of grasses was a little under 2,000,000 acres, producing nearly 3,000,000 tons.

Among the millets and Hungarian grasses the best known are the foxtail or common millets, the broom-corn millets, barnyard millet, and pearl millet. The former are the most commonly cultivated, and all of them produce not only a large amount of forage but large quantities of grain. The millets are all hot-weather plants, but are exceedingly drought-resistant. They will grow luxuriantly on poor soils, but respond well to richer soils. Many of these grasses could be easily improved both for seed production and for forage and hay, but so far very little attention has been given to them.

---

[a] Twelfth Census of the United States, 1900, Vol. VI, Agriculture, pt. 2, p. 21

Para grass—Recently Para grass, a South American *Panicum*, has given excellent yields along the Gulf coast and in Florida. Its culture is rapidly extending westward, especially in southern Texas. It has a great advantage over Bermuda grass or Johnson grass, as its runners are on the surface and can be easily destroyed, whereas in the grasses mentioned the runners have a tendency to go rather deep, so that they are difficult to eradicate from cultivated land and, for that reason, are much in disfavor. The Para grass, however, can not stand much cold at the present time. It will doubtless, however, gradually be pushed farther north and may become one of the most valuable forage and hay grasses for moist or wet lands. In Florida Para grass has carried as high as 6 head of cattle per acre for eight months of the year.

Guinea grass.—This is a closely related species introduced from Africa. It grows more as a bunch grass, is adapted to drier lands, and is a highly prized grass, especially in Florida, Alabama, and Mississippi.

Crab-grass.—The crab-grass of the South, though considerable of a weed, makes excellent volunteer forage and very good hay.

Bermuda grass.—The most common lawn and pasture grass of the South is the Bermuda grass. It produces a very fine quality of hay, is an excellent sand and soil binding grass on account of its strong rootstocks, stands pasturing well, and is quite resistant to cold.

Bluegrass.—In the North the Kentucky bluegrass is the principal cultivated pasture grass and lawn grass. It is especially adapted to limestone soils.

Timothy and redtop.—In the North the principal hay grasses are timothy and redtop, the former adapted to the higher and drier lands, and the latter to the moister situations.

Other wild grasses.—In the West the principal wild grasses are the blue and white grama, mesquite, buffalo, and the bunch grasses, the big bluestem, and the western wheatgrass. A large number of other genera and species, however, are of great importance as adapted to special conditions, especially to high altitudes, to alkali, and to withstand drought, many of the most valuable species, like buffalo grass, curing as they stand on the ground, making an excellent winter feed.

As previously stated, many of these wild grasses have been almost destroyed in parts of the range country, owing to overstocking, but it has been found that, if the range is rested and if the wild grasses are allowed to seed for a few years, they can easily come back to their former luxuriance. Observations made by Mr. Coville in connection with the Forest Service show that it is often necessary to keep the stock off the range only for a short period, while the more important grasses are forming their seed. After the seed is formed, the range may be again used without serious injury to the grass flora. Taking advantage of this fact promises to be one of the most important elements in range management.

Great improvements can be made by selection, not only in our native grasses, but in the introduced species. Their value and adaptation to certain areas can by this process be very greatly increased. Grasses respond also readily to fertilizers, especially to nitrogen and phosphates.

Next to the legumes, the grasses are the most important soil-improving crops, provided a considerable portion of the stubble or the sod is occasionally turned under or allowed to rot on the ground, thus forming humus. Under these conditions in limestone soils, if the proper bacteria are present, large quantities of atmospheric nitrogen are fixed by the bacteria, the carbon required in the process being furnished by the dead grasses. None of the grasses, however, so far as known, have symbiotic bacteria growing on their roots, as in the case of legumes.

LEGUMINOUS FORAGE CROPS.

Clover.—Of the leguminous forage crops, the most important are the clovers in the Northeast and North Central sections, cowpeas in the Southeast and South Central States, and alfalfa in the West. There are about 250 species belonging to the true clovers, genus *Trifolium*, about 65 of which are native in North America, the greatest number being in the Western States. Many of these are extremely valuable as elements in the native forage and as soil-improving, nitrogen-fixing crops.

The most valuable cultivated species, however, are the introduced varieties—red clover, mammoth clover, crimson clover, alsike, and berseem. Of these the red clover is the most important and the most widely cultivated. It has many strains as the result of cultivation under different conditions, but up to the present time very little attention has been given to selecting and adapting varieties to localities.

Clover requires a well-drained soil containing considerable lime. It is extremely sensitive to acid reaction in the soil or to a lack of potash or phosphoric acid. It also requires, like the other legumes, certain types of bacteria, which form nodules on the roots and secure nitrogen from the air for the use of the plant. Occasionally these bacteria are not present in the soil or are of reduced vitality or nitrogen-fixing power, and clover fails to do well until the soil is reinoculated.

In the South a root and stem disease has destroyed large areas of red clover, and the disease, living in the soil, prevents the growth of clover on those soils. The Tennessee station has found that strains resistant to this fungus can be developed, and such selected strains of clover grow well in soils where the ordinary types die out completely. The large number of species of clovers which hybridize readily makes it possible to produce strains adapted to a very wide range of conditions and agricultural requirements.

Crimson clover is cultivated especially in the South Atlantic States north of the cotton belt and south of the fortieth parallel. It is grown principally as a cover crop in orchards for soil improvement.

In the Southern States the principal legume grown for hay and for soil improvement, as well as for the seed, is the cowpea. There is a large number of varieties of cowpea, probably originally developing from a single species, *Vigna sinensis* (a bean rather than a pea). Unlike the clovers, the cowpeas are well adapted to soils inclined to be acid, but are, nevertheless, prolific nitrogen fixers, provided they are supplied with the proper bacteria. The cowpea, however, is peculiarly subject, on light soils, to attacks from the nematode rootworm, causing galls on the roots, and to a disease known as wilt. The culture of varieties susceptible to these diseases is likely to infect the soil to such an extent that other crops sensitive to these diseases can not be developed, and even the peas themselves fail to grow. The only crops not injured by root-knot are the grasses and grains. The disease is very injurious to vegetables, fruit trees, and cotton, and many thousands of acres have been practically ruined for these crops by the development of nematodes in connection with the cowpea. As the cowpea, however, is absolutely essential as a soil-improving crop, it was necessary to find a strain resistant not only to the nematode but to the wilt. This was accomplished in the variety known as "Iron," which is extremely resistant to both diseases and can be used with perfect safety on soils infected with the diseases or without danger of introducing disease to soils not infected. The Iron cowpea, therefore, is the key to the improvement of the lighter, sandy soils in practically all the Southern States. Its resistant qualities have now been bred into a number of other strains of cowpea, but these have not yet come into commercial use. It is possible, however, to produce resistant strains which give high yields of hay and seed and which are adapted to the various localities. Much interest is now being taken by experimenters in this work.

Alfalfa or lucern (*Medicago sativa*).—This is the most important leguminous hay and forage plant of the West. It was introduced into California from Chile in 1854, and spread first through the irrigated sections. Some of the varieties are especially adapted to irrigated lands, on which they give extremely high yields. It has been grown more or less in every State of the Union, although it is only in the West and Southwest that its culture has reached large proportions. Until very recently alfalfa was supposed to be practically one species, but more careful study has shown that there are probably several species and a very large number of varieties, much of the commercial seed being considerably mixed.

The ordinary alfalfa or purple lucern is widely cultivated all over Europe and Asia and has hybridized to some extent with other species native in those regions, especially with the yellow form, *Medicago falcata*, growing in the north of Europe. The latter species has yellow flowers and is extremely cold resistant. These hybrids, known as *Medicago media*, combine the fine hay qualities of the ordinary alfalfa with the cold and drought-resistant qualities of the yellow northern form and are thus much better adapted for growth in such localities. Some of these hybrids are known under the common name of sand lucern and are found to be well adapted to northern Michigan, Minnesota, the Dakotas, and Montana. A similar intermediate form has been found in Turkestan, and is probably a hybrid between the yellow form of northern Siberia and the dry-land strains of the ordinary alfalfa growing in Turkestan.

Alfalfa adjusts itself to climates and soils with considerable facility and, where it has long been cultivated under peculiar climatic conditions, it adapts itself to these conditions. Extremely valuable sorts or strains may thus be secured from many Old World localities, and these strains when introduced into similar conditions in the United States are proving of more value than the ordinary unadjusted or unadapted sorts. It is absolutely essential, however, in introducing these strains to know the exact conditions to which they are adapted; otherwise they will simply break up and require acclimatization again. An American adaptation of this kind has been found in northern Minnesota and has been distributed under the name of Grimm alfalfa. This is an acclimatized strain of ordinary alfalfa, possibly having a slight admixture of the northern yellow species *falcata*. In any case, it is an extremely valuable cold-resistant sort.

A strain of alfalfa secured in an oasis of the Sahara Desert is extremely alkali resistant and may prove valuable for such locations.

A careful study of the varieties and adaptations of this important class of leguminous crops is now being made by the Department of Agriculture, experiment stations, and practical farmers, and great improvements will undoubtedly soon be made in the adaptation of these varieties to varying conditions. There is no doubt that strains well adapted to culture in the Eastern and Southern States can be developed. The alfalfas are perennial, deep-rooted crops, strong nitrogen fixers when supplied with the proper bacteria, and extremely valuable not only for forage and hay but as soil improvers, making large amounts of humus and fixing large quantities of atmospheric nitrogen.

The nodule bacteria adapted to alfalfa are rather more sensitive to unfavorable soil conditions than the types adapted to other legumes, and greater difficulty is therefore found in inoculating seed for sowing in areas where the germ is not present. For this reason inoculation with soil has proved more certain in many cases than culture inoculation, and where soil can be obtained free from injurious weeds or diseases this method is to be recommended.

The worst pests of alfalfa, however, are weeds, especially the dodders and wild barleys and other grasses. The alfalfa leaf-spot and anthracnose (the same disease which attacks clover) are often quite destructive in the Southeastern States, where root nematodes also do considerable damage to this crop. In the Southwest the root-rot, *Ozonium*, which attacks cotton, also attacks alfalfa, and, as all these pests are readily distributed through soil, it is considered a dangerous practice to distribute soil for the purpose of inoculation, except from very carefully controlled fields, which are hard to find. The Department of Agriculture supplies pure cultures, and with a little care these can usually be made to work satisfactorily. Wherever sweet clover grows the sweet-clover germ present in the soil works satisfactorily on alfalfa, so that inoculation is not usually necessary.

The vetches.—Two of the twenty or more species of vetches have been used considerably in this country as cover crops and for soil improvement and hay—spring vetch or tare (*Vicia sativa*) and the winter, hairy, or sand vetch (*Vicia villosa*). The former is cultivated to some extent in New England and in Washington, Oregon, and California. The winter vetch, or hairy vetch, is much better adapted to the agricultural requirements of a winter cover crop than the former species and is coming to be widely used for that purpose.

Very cold-resistant strains of this winter vetch have been introduced from northern Europe and have been adjusted to the conditions in New England. It also grows quite successfully through the Middle States and the South. It produces a mass of fibrous roots, which when inoculated produce abundant root tubercles. It does not seed well unless inoculated. Although it does best on good soil it makes an excellent growth on poor sandy, gravelly soils, where it produces a heavy growth of nodules.

The importance of inoculation on poor soils is shown by the results secured at the Alabama station. Without inoculation it produced only 232 pounds of hay per acre, but with inoculation it produced 2,540 pounds. At the Cornell station over 6,800 pounds of air-dried forage per acre were produced in three months, and even higher yields than this have been produced in many localities. This winter vetch is not only cold resistant, but also resists drought and is not subject to serious injury from diseases or insects. It is, therefore, one of the most promising of our winter cover crops both from the standpoint of soil improvement and forage as well as hay.

Other valuable legumes.—In the cotton States the velvet bean (*Mucuna utilis*), the Florida beggarweed (*Desmodium tortuosum*), Japan clover (*Lespedeza striata*), and the bur clovers (*Medicago maculata* and *M. denticulata*) are all valuable cover crops.

A large number of other legumes, both native and introduced, are being experimented with by department and experiment station workers, and it is believed that leguminous cover crops and soil-improving crops can be found for every locality and condition required. These, with the proper bacteria present, ought to supply not only the soil humus so necessary to the maintenance of fertility, but they should fix from the atmosphere the nitrogen required for our other cultivated crops and grasses. The improvement of these leguminous cover crops is rapidly being pushed, and as agricultural conditions settle down to greater permanence their use in rotations will be greatly increased.

In this connection should be mentioned also legumes grown for seed. These are also valuable soil improvers, as, after the seed is gathered, the hay can either be used for stock feeding or turned under. All of the legumes already mentioned are more or less grown for seed, but in addition to these the common pea in its various varieties, the cowpea, the soy bean, peanut, and horse bean (*Vicia faba*) are all largely cultivated. There is a very great number of varieties of these crops adapted to different conditions, all of which can be very greatly improved by breeding and selection.

SUGAR-PRODUCING CROPS.

Sugar beets.—Of the root crops the most important are the various varieties of beet. Some of the white varieties of beet contain high percentages of sugar and are cultivated under the name of sugar beets, especially in the North Central and Northwestern States, where the days are cool and bright. Formerly the seed for the highly selected strains of sugar beets was imported, but in late years, through the effors of the Department of Agriculture, strains have been developed specially adapted to the northwestern conditions, which give better results than imported seed.

The principal drawback to sugar-beet culture in the United States is the large amount of hand labor required in thinning the beets, as the seed balls have from two to five germs in each ball and all but one of these has to be broken off after the seed sprouts. The department has under way a breeding experiment for the production of single-germ seeds, so that each ball will produce but one sprout. Strains have already been secured which produce more than 60 per cent of these single-germ balls, and it is believed that ultimately strains of high sugar-producing sorts of beets can be developed which can be planted by machinery and thinned by machinery, thus greatly reducing the amount of labor in the culture of this crop. When this is accomplished, the industry of sugar-beet growing in the United States will be very greatly stimulated, and it is possible that not only our home demand for sugar can be supplied but that we can compete in the foreign markets.

Sugar cane.—The sugar cane of the South is also an important sugar-producing plant, but very little attention has yet been given to its improvement. From the results of work done in the West Indies and to some extent by experimenters in this country, it seems probable that considerable improvement can be made in the productiveness and unformity of American cane.

The soil and climatic conditions of Louisiana and the cane-growing sections are not as favorable to the growth of this crop as are those of Cuba, Porto Rico, Hawaii, and other tropical islands. The cost of drainage and the occasional cold waves, the high cost of seed cane, and the lower yield per acre in Louisiana, make the cost of sugar per pound very much higher than in the other countries named. Unless some improvement can be made in the methods of handling this crop in the Southern States it is doubtful if it can do much more than hold its own in competition with other cane sections now in possession of the United States. As shown by the census reports, the development of the sugar industry in Hawaii has been phenomenal since close trade relations have been established between the islands and the United States. With the development of irrigation works it is probable that considerable land not now cultivated can be brought under cultivation for cane and that the amount of sugar supplied by the islands can be considerably increased. The same is also true in Porto Rico, the Philippines, and Cuba.

According to the latest statistics gathered by the Department of Agriculture, the production of the cane sugar appears to be about just holding its own from year to year, while the production of beet sugar has considerably more than doubled in six years. The total annual consumption of sugar in the United States has reached nearly 3,000,000 long tons, and about 80 per cent of this is imported either from foreign countries or from the insular possessions of the United States. The total consumption of sugar has increased about 140 per cent, while the per capita consumption has increased 52 per cent since 1884. It is evident, therefore, that there is great opportunity for the development of the sugar industry not only in the United States but in our insular possessions.

Saccharine sorghums.—Another source of possible sugar production on the basis of farm crops is in the utilization of the saccharine sorghums. These have already been briefly referred to and attention called to the difficulties of obtaining from sorghum cane cheaply a good quality of sugar. The juice of the sorghum cane, as extracted by the mill, shows, in addition to sugar and water, considerable starch, dextrine, and soluble salts, which interfere with the crystallization of the sugar. Some of the better quality of cane, however, contains over 12 per cent of cane sugar and only 0.6 per cent of glucose. Almost no attention, however, has ever been given to the question of the careful breeding of canes for the purpose of cane-sugar production. With improvements in the methods of extraction which have been made in the past few years, especially through the efforts of the Department of Agriculture, and with the improvements which will be entirely possible as the result of careful selection and breeding, it is believed that the growing of sorghum cane for sugar will in the future be fully as profitable in the Southern States as the culture of beets in the Northern, and this crop may be considered as one of the important potential sugar crops of the United States. The cane is now cultivated in small areas on nearly 500,000 farms in the South, but it is used principally for sirup. These figures do not include a considerable acreage of the saccharine sorghums grown for forage. Nearly 17,000,000 gallons of sirup were produced in 1899, valued at over $5,000,000.

Maple.—According to the last census, the quantity of maple sugar made in the United States in 1899 was nearly 12,000,000 pounds and over 2,000,000 gallons of sirup.

FIBER CROPS.

Practically all of our cultivated plants produce more or less valuable fiber. The immense quantities of cornstalks now going to waste, in addition to what are used for other purposes, produce very valuable fibers for paper manufacture, and recent investigations and discoveries have led to the belief that the stalks may possibly be utilized to replace wood pulp now largely used in cheap paper manufacture. A method of separating the pith from the fiber cells has recently been discovered which appears to make the utilization of stalks for this purpose practicable.

Flax.—The oldest of our fiber plants is probably flax. Flax culture was early introduced into America, but has always been conducted along the most primitive lines. The farm methods have been crude and very irregular; the crop was grown year after year on the same soil without rotation, so that even at the present time the crop has no permanent place in the agriculture of the country. It is usually grown on new land for one year, sometimes two, after which the soil is said to be "flax sick" or exhausted, and the crop is moved to a new area. In this way it has been an important crop in a number of the older States, gradually moving westward to new lands, and is now centered in North Dakota and South Dakota.

The total area of flax in the United States is in the neighborhood of 3,000,000 acres (1907). There is considerable fluctuation in the acreage from time to time. In 1903 it was approximately 3,700,000. In this country flax is grown almost entirely for its seed for the purpose of extracting the oil. Between 25,000,000 and 30,000,000 bushels are annually produced, with an average yield fluctuating between 8 and 11 bushels per acre.

One of the principal reasons that the fiber has not been utilized has been the fact that the crop must under present agricultural conditions be grown on new land, and for that reason the center of production has been in constant movement from year to year. It has now been discovered, however, through the work of the North Dakota Experiment Station that flax sickness is not due to the exhaustion of the soil, but to the presence of one of the wilt fungi, a parasite which getting into the roots destroys the plants. This wilt fungus is very closely related to the one causing the wilt of cowpeas, cotton, and other crops in the South. A strain of flax resistant to this disease has been developed and produces excellent crops on infected soils where the ordinary flax will not grow. This promises to establish flax culture upon a firm basis, and, with the development of general farming systems, including rotation methods, and improvement of the fiber qualities of the flax, it is believed that strains valuable not only for oil but for fiber can be very profitably grown, at least in the moister portions of the North Central States.

The finest varieties of fiber require rather moist air and soil not subject to severe drought, and with a high humus content. It is probable, therefore, that the finest fiber flaxes will be produced in the moister portions of the country, while the oil or seed flax may be more successfully grown in the drier sections. However, even the straw in the drier regions can be utilized for tow, for paper pulp, binder twine, crash toweling, bagging, etc., and, as the industry becomes more stable, factories are developing to utilize the waste straw in this way.

COTTON.

The fiber plant of greatest importance, not only to America but to the entire world, is cotton. There are about 24 recognized species of cotton in different parts of the world. Many of the species cross readily, so that wherever they have been brought together there are many intermediate types. The American Upland cotton, which constitutes the bulk of the cotton of the world, comes from a species (*Gossypium hirsutum*) native in Central America. The plant is a perennial but both in its native habitat and in the United States it is cultivated as an annual.

Sea-Island cotton.—The Sea-Island cotton, *G. barbadense*, is apparently indigenous in the West Indies. It is of larger growth than the upland cotton and has a much longer and finer fiber. Its culture is practically limited to the moister coast regions of the South Atlantic States, the finest grades of it being produced on the sea islands in the neighborhood of Charleston and in the more healthful portions of the coastal plain in Alabama, Georgia, and northern Florida. The average production for the past seven years has been about 94,000 bales annually. The plant requires the most careful selection in order to maintain the high quality of the fiber. A few years ago many of the finest soils for this plant in the sea islands became unprofitable for the growth of this crop, the cotton dying before maturity. This was at first supposed to be due to the exhaustion of the soil in some particular, but investigation showed it to be due to a wilt fungus similar to that attacking cowpea, and resistant strains of Sea-Island cotton were bred which produced excellent crops even on the worst infected land. This again placed the industry on its feet, but the growers in the sea-island region have combined and allow no seed of their selected strains to be sold outside the district.

The sea-island growers outside the district have not been so progressive in the matter of selection, but are waking up to the necessity now that they can not secure seed from the Charleston district. Through the efforts of the Department of Agriculture it has been demonstrated that the strains for inland culture can be improved in the same manner as the Sea-Island strains and that wilt resistance, which is as fully if not more important in the interior districts, can be developed and maintained by selection.

The demand for Sea-Island cotton is somewhat limited, and excessive stimulation of production is therefore not desirable, as much reduction in price would make the crop unprofitable owing to the great care required in its production.

Egyptian cotton.—A closely related type of cotton, if not the same, is the Egyptian. The Egyptian cottons are cultivated principally in Egypt, but considerable quantities are imported into this country for special uses. The plant has now been acclimatized in the irrigated regions of the West and yields an average of a bale to the acre of a very good quality of fiber, but has not yet reached the stage of commercial production. About 100 bales will be marketed during the present season.

Long-staple Upland cotton.—The only other long-staple cottons produced in the United States are the so-called long staple Uplands now grown mainly in the alluvial delta region of Mississippi and Louisiana and to a limited extent in the rich valleys of the Red River in Texas and Louisiana and in similar localities in other cotton States. The crop of these cottons constitutes about 100,000 bales. The origin of the long-staple Uplands is probably the result of hybridization between the ordinary Upland cotton and the Sea-Island species. A number of fairly well-known strains are now in culture—Allen Hybrid, Allen Improved, Cook, Doughty, Griffin, Improved Long Staple, Mathews, Moon, and Columbia (the latter developed by the Department of Agriculture), Peeler, Southern Oak, Sunflower, and other varieties. Little attention has been given to the development of long-staple strains, as the premium paid for them has not been sufficient to warrant. The Sea-Island blood in them has had a tendency to make the long-staple strains rather late in maturing, which has not up to the present time been a drawback, but now that the boll weevil has such a firm foothold it will either be necessary to develop strains of the long staples of quicker maturity than those now grown or give up the culture of these cottons altogether, as production in the presence of the weevil demands quick maturity. The department has developed some hybrids between Upland and the long staples which appear to be as quick maturing as the Uplands and have done well in the river bottoms of southeastern Texas, maturing sufficiently early to escape serious injury from the weevil.

Upland cotton.—The great bulk of American cotton, however, as previously stated, comes from the Upland sorts, of which there is a large number. Cotton adjusts itself gradually to variations in soil and climate, and to secure the best results it is necessary to carefully select and breed seed in the region where it is to be grown. Almost no attention, however, has been given to this matter in cotton culture. The practice has been to get seed from the gin, and therefore mixtures of different strains were secured, often of poor quality and low yielding power, with the result that the average yield throughout the cotton States is very greatly below what it could easily be made by a little care in the selection of seed and the adaptation of the strains to the conditions of culture. Since the advent of the boll weevil much more attention has been given to this subject, and strains have been developed and improved both for quick-yielding and maturing qualities as well as for high quality of fiber or lint. Quick-maturing strains, like Triumph and King, have given very satisfactory yields even in the presence of the boll weevil, maturing the crop early enough to escape serious weevil injury.

In the original home of the American Upland cottons it has been found by department investigators that there are varieties of cotton having adaptations which enable them to resist weevil attack. The more promising strains of these have been brought into the country and are being tested both for their use in breeding and for their individual value for cultural purposes, and as these types were the originals from which the American cottons came, it is probable that some valuable characters can thus be secured, especially along the line of avoiding weevil injury.

Upland cotton is also subject in the Southeastern States in sandy soils to the same disease that attacks the Sea-Island cotton, namely, the wilt. The disease is quite widely spread and annually causes a large loss. Two types of Upland cotton resistant to this disease have been developed and are now being distributed by the department. These types give excellent yields on soils infected with the disease, as well as on other soils.

Cotton responds readily to selection and to better cultural methods. For many years the crop has been grown without rotation and with very shallow and imperfect cultivation and the use of large quantities of commercial fertilizer. All of these practices have resulted in the depletion of the soil humus to such an extent that the soil now packs and washes badly in nearly all the cotton States. It has been demonstrated, however, by good farmers and by numerous experiments by the state stations and the Department of Agriculture, that the plowing under of legumes and the use of barnyard manure and winter cover crops will quickly improve the soil by increasing its humus content, so that with much less commercial fertilizer it will produce more than double its present yield of cotton. These methods, coupled with more attention to the selection of seed, could easily raise the yield of cotton to more than double the present figures on the same acreage, and at the same time produce a number of other valuable money crops in rotation.

The United States now produces nearly 11,000,000 bales, which is more than 65 per cent of the total cotton crop of the world; British India produces something over 2,000,000 bales, a little over 14 per cent of the world's crop; Egypt produces a little over 1,000,000 bales, nearly 8 per cent of the world's crop; Russia, China, Brazil, Mexico, Peru, Turkey, Persia, and several other countries produce small amounts of more or less special types, for which there is a comparatively small demand. It is not probable that any other country will ever seriously compete with the American Upland cotton, especially if some attention is given to the improvements above suggested.

Miscellaneous fiber plants.—A large number of other fibers, including hemp, jute, ramie, etc., could be produced and are grown to some extent in the United States, but their importance has not been sufficient up to the present time to make them compete with other more valuable crops. Hemp is the most important of these and is grown to a considerable extent in Kentucky.

DRUG AND MEDICINAL PLANTS AND NARCOTICS.

The culture of drug and medicinal plants has not been developed extensively in the United States, but interest in this class of crops has been growing in recent years.

Camphor.—It has been shown that camphor can be profitably produced in Florida, the Carolinas, and possibly in Texas, and the beginning of an important industry in the growth of this tree is now apparent.

Opium poppy.—The culture of the opium poppy, which has heretofore been confined in this country simply to the production of poppy seed, will be stimulated to some extent by the discovery of a direct process of extracting morphine from the capsules, leaving out entirely the opium stage, which is so objectionable. This industry will be best adapted to the sections where the poppy is now grown principally for seed, namely, California, Oregon, and Washington.

Other drug plants.—A large number of other native and introduced drug and medicinal plants have been tested in different sections of the country and small industries in their culture will doubtless soon develop.

Tea culture.—Of the narcotics, tea has been commercially produced in South Carolina, and the extension of its culture will depend largely upon the development of machinery to supplement hand labor and reduce the amount of hand labor required. This has now been accomplished in practically all of the curing processes, and one of the department experts has about completed a pruning machine, and a picking machine will soon be developed which will practically reduce the production of tea to a machine basis. When this is accomplished it ought to become as important a crop in the South as tobacco.

Tobacco.—At the time of the discovery of America, tobacco was used for smoking, for snuff, and for chewing by nearly all the tribes of Indians in North America and Central and South America, including the West India Islands. There are about 50 species of the genus *Nicotiana* found in the wild state. All but two of these are found in America. The culture and use of tobacco undoubtedly originated in very early times on this continent, and from the earliest settlement it has been an important crop in several of the New England, Central, and Southern States. Practically all of the cultivated agricultural varieties originated from the species *Nicotiana tabacum* from South America. It is possible, however, that some of the strains may have the blood of a species which grows wild in Connecticut, New York, and Colorado, *N. rustica.* In the early days of the industry, especially in Maryland and Virginia, tobacco was grown year after year on the same land until the soil failed to give profitable returns, when the land was abandoned and allowed to grow up to brush and wood. Many thousands of acres of such old abandoned tobacco farms are still to be seen in these States now mostly covered with old field pine.

As tobacco is cultivated for the texture, size, and quality of the leaf, it is very greatly influenced by conditions of soil and climate, and the greatest care has to be exercised in the selection of soils for the production of the finer varieties, especially the cigar tobaccos. Most of the varieties now in cultivation are adaptations to peculiar soils and climates, and through long culture have come to be well-established types adapted to different uses. Among these may be mentioned the cigar-wrapper types, the cigar fillers, the chewing and plug, and the heavy export types.

Of the cigar-wrapper tobaccos the so-called Sumatra type, which produces a medium-sized, thin, elastic leaf when grown on light well-drained soils in the Connecticut Valley, Florida, and southern Georgia, is the standard. This variety produces the best grade of domestic cigar wrappers. It is grown under shade extensively in Florida and southern Georgia, and recently types have been secured which give satisfactory results in Connecticut. The so-called "Uncle Sam Sumatra," which is a strain of this type produced by the Department of Agriculture, is said to be the most uniform and highest yielding strain of Sumatra ever produced and is now cultivated extensively in Florida and to a considerable extent under shade in Connecticut. Connecticut Havana is a variety largely used for cigar wrappers and binders and the poorer leaves for fillers. It is adapted to light sandy soils when grown for wrappers, and to clay soils when grown for fillers. The light soils make the leaf thin and elastic, while the clay soils make the leaves heavier, thus producing a leaf better adapted for fillers. The Connecticut Broadleaf or Connecticut Seedleaf is a type very largely grown in outdoor culture in Connecticut and is adapted to sandy loam soils. The leaves are very broad, thin, and elastic and have small veins. The quality of wrapper and binder secured from this type of tobacco is not as good as that from the other types mentioned, although it has high yielding power and its adaptability for culture under northern conditions makes it a very desirable leaf for Connecticut, New Hampshire, Vermont, New York, Pennsylvania, Ohio, Wisconsin, and to a small extent in other States. Its quality has recently been very much improved in certain hybrid types between this tobacco and the Havana developed by the Department of Agriculture. It is believed that these new hybrids, which are now beginning to be grown in Connecticut and New York, will ultimately replace the old types.

Of the cigar-filler tobaccos the Cuban variety is the leading type adapted to sandy soils with a clay subsoil; has a small leaf of fine texture and produces a fine flavor and aroma. In the Connecticut Valley this type is also grown under shade for wrappers as well as fillers. Zimmer Spanish, which is probably a hybrid between the Connecticut seed leaf and a Cuban variety, is the principal cigar-filler tobacco grown in the Ohio Valley and Wisconsin.

Of the plug tobaccos the White Burley, the Orinoco, and Yellow Mammoth, and the Virginia tobaccos, Blue Pryor, Sun-Cured, and White Stem, are the leading types, grown especially in Kentucky, Ohio, Tennessee, and North Carolina.

Of the pipe tobaccos the bright yellow types of North Carolina and southern Virginia are leading sorts. These tobaccos are produced only on light sandy soils. On heavier, richer soils they produce a dark-curing leaf. The demand for this type of tobaccos is rapidly increasing, especially for export. The Maryland smoking tobaccos are largely export tobaccos. They develop best on clay loam and sandy soils. The leaves are thick and coarse in texture. The variety was discovered in Maryland when the first settlers explored the region and has extended from Maryland to Virginia and Pennsylvania, and from this type quite a number of important strains have developed in these States.

In recent years great attention has been given to the fertilization of tobacco, especially the finer wrapper and filler sorts. On account of the influence of soil on the quality of the leaf the tendency has been in all the areas producing the finer wrapper and filler tobaccos to grow the crop continuously upon the same land without rotation, and, although great care is used in the composition of the fertilizers, the tendency has been to use excessive amounts. The wrapper and filler types of tobacco do not grow to the best advantage on soils rich in carbonates, so that soils very rich in lime have to be avoided for this class of tobacco. In the Connecticut Valley the extensive use of carbonate of potash and other fertilizers containing carbonates has resulted in the accumulation of these to such an extent in the soil that the feeding roots of the tobacco have been slightly injured, making them sensitive to a fungous disease, which in the past few years has greatly reduced the yields over large areas. The fungus occurs commonly in leaf-mold and decaying organic matter and to some extent on injured roots of tobacco, but does no harm except when the soil becomes decidedly alkaline. It has been found that by using no lime on the diseased fields, applying potash in the form of the sulphate and using phosphoric acid in the form of the acid phosphate or dissolved bone, the alkalinity is overcome and the disease prevented.

The method of culture and fertilization followed has also in many soils very greatly reduced the humus content. This in some cases has been partially avoided by the use of barnyard manures, but on the finer types of leaf these manures stimulate too rank a growth. Experiments conducted in the past few years by the department have demonstrated that hairy vetch used as a winter cover crop for tobacco soils greatly improves the leaf texture, supplies the necessary nitrogen and humus, and improves the soil greatly for the production of the better types of leaf. Yields of over 7 tons of vetch per acre have been secured from inoculated seed. The nodule organism for vetch is not found in tobacco soils generally and the crop does not give good results except where the germ is supplied. Tobacco following uninoculated vetch shows but little advantage over that following a cover crop of rye. In comparative tests the inoculated crop yielded 7 tons as compared with the yield of 2 tons uninoculated, and the nitrogen content of the inoculated crop was very much higher than that of the uninoculated. Where a sufficient supply of humus is present in the soil the tobacco crop is not only larger but better in quality and more uniform.

In the South a bacterial disease has accumulated in some of the tobacco soils as a result of continuous culture without rotation, and in some places root nematode has developed to such an extent that the soils will no longer produce a profitable crop. In the latter case a resistant strain of tobacco has been produced by selection which grows well on nematode infected soils, but no strains resistant to the bacterial disease have yet been secured. The same bacterial disease also attacks potatoes and tomatoes, which are among the profitable crops grown on the same soils in Florida. It is useless, therefore, to rotate with these crops where this disease is present.

In the areas growing heavier types of tobacco, especially in Maryland, Ohio, Kentucky, Virginia, and the Carolinas, the principal problems involved in the improvement of the crops are along the line of rotation. The tendency is to cultivate tobacco too long upon the same land without rotation and without proper fertilization. The experiments conducted by the department have shown that the yield can be very greatly increased by rotation systems and by the use of fertilizers where the lands are deficient in any of the necessary elements, as they often are in nitrogen, potash, and phosphoric acid. In all sections the experiments have shown that great improvements can be made in the tobacco crop by careful selection. Tobacco is cross-fertilized by insects, so that in order to secure uniformity in product it is necessary to prevent insect visits to the flowers. In view of the fact that the tobacco is perfectly self-fertile, this is easily accomplished by bagging the flower stalks before the flowers open. In this way, by carefully selecting the mother plants, it is possible to produce improved strains of great uniformity, and as a few plants produce all the seed required for a large crop, the use of this bagging system, introduced by the department several years ago, has already resulted in the development of strains of superior quality and much higher yield.

The work of the department has also demonstrated that it is possible to separate the light from the heavy seed in order to produce greater uniformity. A simple device for this purpose has been patented by the department and is now in wide use among the tobacco growers.

Great improvements in the quality and quantity of the marketable crop have been secured by better methods of curing and fermentation. A discovery made by one of the department experts of the relation between nicotine and the quality of tobacco has shown that the sharp biting quality which the leaf often has is due to an excess of free nicotine, and that in the better types of tobacco, although the total nicotine may be equal to or higher than the biting types, it is combined with an organic acid, usually citric or malic. Spraying the leaves during fermentation with a dilute solution of these acids, sufficient to neutralize the free nicotine, greatly improves the quality of the fermented product in cases where the normal citric acid content of the leaf is not sufficiently high to accomplish this.

The production of wrapper and filler tobaccos has been rapidly extended of late years in Florida, Georgia, Alabama, and Texas. Many farmers have gone into the culture of this crop without due consideration of the difficulties involved. The result has been that in the last two years, especially, large quantities of low-grade leaf have been produced—due in part also to unfavorable seasons—and much of it still remains in the hands of the farmers, there being no sale except for the better qualities. This illustrates the danger of too rapidly expanding the culture of a crop requiring such skill and judgment as the production of tobacco of the higher grades.

The total acreage of tobacco in the United States has considerably decreased since 1903, the 1907 area being about 200,000 acres short of the acreage for 1903. The average yield per acre, however, has gradually increased, though the total production as the result of decreased acreage is slightly less than in former years. The average farm price per pound, however, has gradually increased. The domestic exports have remained fairly constant, while the imports of manufactured tobacco have slightly increased. Both the area and the yield in all our types of tobacco can be readily increased as fast as the demand warrants and the price is remunerative.

Hops.—Brief attention should be called to hop production. The United States is becoming an important hop-producing country, though the quality of American hops is somewhat inferior in the estimation of some to certain types produced in Europe. Little attention has been given to the improvement of varieties, and preliminary studies indicate that great improvements can easily be accomplished in quality and in yield. The quantity produced in the United States ranges between 40,000,000 and 60,000,000 pounds annually. The export trade in hops is gradually increasing, nearly 17,000,000 pounds having been exported in 1906. The imports of special qualities of hops, however, amount to between 6,000,000 and 10,000,000 pounds.

POTATOES.

Irish potatoes (*Solanum tuberosum*).—The species to which the potato belongs has been cultivated in the high plateaus of Peru for probably two thousand years or more. It was carried from Peru to Spain, from which country it was probably introduced into North America. Since the discovery of America the potato has rapidly spread into all countries to which it is adapted, especially the cooler temperate regions, until it has become one of the most extensively grown and most valuable food crops of the world, with an annual yield of approximately 5,000,000,000 bushels. According to Fraser,[a] 1 acre of potatoes frequently furnishes as much human food as 10 acres of wheat. Wherever wheat is a precarious crop, as in northern Europe, potato growing has been extensively developed. Yields of 1,000 to 1,200 bushels of potatoes per acre, containing 10,000 pounds of starch, are on record. The average yield for Russia is about 95 bushels per acre; Germany, about 200 bushels; England, 230 bushels; Ireland, 150 bushels. The United States produces approximately 3,000,000 acres per annum, with an average yield for the past ten years of 86 bushels annually. The average yield for 1904 was 110.4 bushels per acre and for 1906, 102.2 bushels. The average yield fell down to 65 bushels in 1901, the crop being badly affected by drought in that year in several of the heavy-producing States. The highest average yields are secured in the New England States and in the irrigated portions of the Rocky Mountain and Pacific Coast States.

The potato does best on a deep, mellow, easily worked loam containing a rather high humus content. Ten or fifteen tons of barnyard manure per acre, plowed under in the fall, or cover crops of buckwheat, clover, hairy vetch, or other similar green crop, put the soil into excellent condition for potatoes. However, in all cases the organic matter should be in a thoroughly decayed state before the crop is planted. In the case of old sods there is danger from grubs and wireworms, so that the cover crop for potatoes should not be more than one or two years old. Where buckwheat does well it is considered an especially good cover crop for potatoes, as it leaves the soil in excellent tilth, and remarkably smooth tubers are produced following this crop. Some of the finest potato soils in the United States are the reclaimed tule peat lands of California.

---

[a] S. Fraser; Cyclopedia of American Agriculture, 1907, vol. 2, p. 520.

In all the potato districts there is a tendency to grow the crop year after year on the same soil, with the result not only of humus destruction but the accumulation of several serious diseases of the potato, especially the wilt disease, the bacterial disease, and in the Northeastern States the potato rot and scab. The latter disease is especially caused by the alkalinity of the soil, developing best in soils of an alkaline reaction. The yields during some years and in some sections are often very greatly reduced by these diseases. When the soils become thoroughly infected with these parasites it is difficult to eradicate them, as many of them live for long periods saprophytically. Some progress has been made in selecting varieties resistant to these diseases, but so far the work has had very little effect on the commercial production on account of the fact that no varieties have been developed which have a good market demand and which are at the same time disease resistant.

In the North Central States the so-called early and late blights, due to fungi attacking the leaves, cause in years favorable to these diseases very great loss, but it has been shown that by spraying the crop with Bordeaux mixture it is possible to reduce these losses to a negligible quantity. However, spraying methods are practiced only by the more progressive growers. The same treatment prevents the injury from flea beetles, which otherwise do great damage to the crop, and the use of Paris green with the Bordeaux mixture also prevents the attack of the potato bug, which also does immense damage to crops not protected.

Potato culture is considerably practiced in the South for early markets by importing seed tubers from the North. Southern-grown potatoes are not satisfactory for seed, as the crop is not adapted to hot climates. It is believed, however, that strains could be adapted for culture in the South by the development of seedlings in that region and possibly by hybridizing the *Solanum tuberosum* with some of the other tuber-producing species, as *S. maglia*, which is a native in the coasts of Chile, or *S. commersonii*, a native in Uruguay and Argentina, in rocky and arid situations at low levels. Of the 1,000 species of the genus *Solanum* in many parts of the world, there are about 20 species which bear tubers. It is possible that by combining these with the valuable qualities of the species at present in cultivation its range and adaptation can be very greatly increased, and possibly the food value, especially the nitrogen content of the tubers, can also be improved by this process.

Until within recent years most of the culture of potatoes has been carried on by hand, but potato planters and diggers have now been adapted to this crop, thus greatly decreasing the cost of production.

Sweet potatoes.—The sweet potato, *Ipomoea batatas*, is a member of the morning-glory family and is one of our important vegetable crops of the Southern States. The species from which the sweet potato developed, while not now positively known in the wild state, probably originated in Central or South America, possibly in Peru, where there are records of its ancient existence. It is, therefore, essentially an American crop, but, like the ordinary potato, its culture has extended into many other countries. Related species occur in China and eastern Asia, and its cultivation there may have been coincident with that in South America.

The commercial production of sweet potatoes in the United States extends as far north as middle New Jersey and as far west as Kansas. It is grown extensively under irrigation in southern California. According to the Twelfth Census, the sweet potato is, next to the Irish potato, the most extensively grown vegetable in the United States, and was reported on more than 1,000,000 farms. The acreage, including that of yams, was 537,447, and the value of the crop in 1899 was nearly $20,000,000. The largest production is in North Carolina, Georgia, Virginia, Alabama, and South Carolina.

The sweet potato requires a warm, sandy, well-drained soil, and responds well to fertilizers and manures. A high humus content is essential, as the crop suffers quickly from drought. Crimson clover sod is especially valuable if plowed under while the clover is young. With heavy manuring and fertilizing, sweet potatoes may be grown upon the same land for several years, and this practice is often followed. Several serious diseases, however, result from this practice, especially the so-called black-rot of the roots. The disease does not do so much damage in the field, but when the land becomes infected its presence in the stored potatoes causes them to rot, and in this way it is very injurious. As a rule, however, sweet potatoes are remarkably free from enemies.

The yield per acre depends largely upon the favorableness of the soil, fertilization, and the care and culture of the crop. The yield per acre in the United States averages about 83 bushels for white farmers and about 67 bushels for colored farmers. Yields of three or four times this amount, however, are easily secured where conditions are favorable. The crop is one of increasing importance and is susceptible of great improvement, not only in the matter of varieties but in cultural methods.

The food value of the sweet potato is higher than that of the Irish potato, and its use for feeding to stock is increasing. The principal use of the sweet potato is for the table, and the demand is rapidly growing, especially on the cotton and tobacco lands in rotation with corn, peanuts, and grass.

CASSAVA.

This crop, belonging to the same family as the castor bean, is widely cultivated in the tropics and is probably native to Brazil. The roots produce large quantities of starch as well as considerable nitrogenous matter, making a very valuable food for man and animals.

The culture of the crop has been tried for some years in Florida, but, owing to the fact that the plants had to be propagated from cuttings, which were difficult to produce in a healthy condition, the yield of good plants per acre has been so small as to make the industry unprofitable. The difficulty of propagating from canes led the Department of Agriculture to experiment in the production of a strain of cassava that could be propagated from seeds sown annually. Most of the varieties do not come true to seed, and the results are so variable when the seed is planted that heretofore it has not been adopted as a method of propagation. The department has, however, as a result of several years' selection secured strains which produce readily and uniformly from seed, yielding from 8 to 10 tons of roots per acre. It is believed that the use of these new varieties will make this one of the most important root crops of Florida and possibly of other areas along the Gulf coast. It is valuable not only for stock and as tapioca, for human food, but for starch, glucose, and alcohol manufacture. It is believed that as a source of denatured alcohol it will be cheaper than any other starch-producing plant.

VEGETABLES.

It will not be possible in this paper to discuss individually the very great number of crops grown as vegetables for market. Market gardening in the neighborhood of the large cities has developed at a rapid rate in the past ten years. Over 2,000,000 acres are reported in the last census as having been devoted to vegetable crops on over 615,000 farms. Twenty-five per cent of these farms derive their principal income from vegetables. These crops are produced in the neighborhood of the large markets under very intensive culture, the most careful attention being given to every detail of cultivation, both in the matter of the selection of soils, their fertilization, the selection of seed, and the marketing of the crops. With the increased facilities in transportation, and the great growth of the canning industry, the areas available for market gardening and truck crop growing have been greatly increased in recent years.

FRUITS.

Next to vegetables and flowers and products under glass, the most careful attention has been given in the United States to the production of fruits. According to the last census, the total production for the United States amounted to over $131,423,000. Of this, $83,751,040 represented orchard fruits, a little over $14,000,000 grapes, over $25,000,000 small fruits, and about $8,500,000 subtropical fruits.

Orchard fruits.—Of the orchard fruits, 55 per cent was apples, 27.2 per cent peaches and nectarines, 4.8 per cent pears, 8.4 per cent plums and prunes, 3.2 per cent cherries, and 1.4 per cent apricots. According to the census reports, the apple increased its proportion of the total production of orchard fruits from 76.3 per cent in 1889 to 82.8 per cent in 1899; the pear from 1.6 per cent to 3.1 per cent; the plum from 1.4 to 4.1 per cent; cherries, 0.8 to 1.4 per cent; apricots, 0.5 to 1.3 per cent. Peaches, owing to a complete failure in many sections, decreased from 19.4 per cent to 7.3 per cent. The States which took the lead in 1899 in the value of their orchard products were: California, over $14,500,000; New York, over $10,500,000; Pennsylvania, nearly $8,000,000; Ohio, over $6,000,000; Illinois, nearly $4,000,000; Michigan, nearly $4,000,000; Indiana, over $3,000,000; Missouri, nearly $3,000,000; Virginia, over $2,500,000; New Jersey, over $2,500,000.

These States reported an aggregate value of orchard fruits of over $58,000,000, or 69.3 per cent of the total value of all orchard fruits in the country.

There is an immense number of varieties of all these fruits grown in the United States, some of them introduced from foreign countries and others produced as chance seedlings from time to time here. Our finest apples have largely been the result of seedlings discovered from time to time by different growers. In the early days of the country, before the development of nurseries, many of the orchard trees were raised from seed, and most of our valuable varieties originated during this period of seedling orchards. Later, with the development of nurseries and the bud propagation of the more valuable sorts, the development of seedling varieties gradually dropped into the background. In recent years, however, as the demand for better acclimatized sorts has developed, more attention has been given to the production of seedlings. This is especially true in the northern Mississippi Valley region, where the very cold winters and hot dry summers are very destructive to the tenderer orchard fruits.

A number of serious disease and insect pests attack all our orchard fruits, in the case of the apple and pear especially the bacterial blight and the codling moth. The bacterial blight is very difficult to control and has destroyed the finer varieties of pear in most parts of the United States. Until recently the great Bartlett pear orchards of California were comparatively free from this disease, but within the past few years it has been introduced and has destroyed more than $5,000,000 worth of orchards, representing about one-third of the pear industry of that region. Methods for controlling the disease have been worked out, but they are not yet entirely satisfactory.

The various leaf diseases and the diseases attacking the fruit can be controlled by spraying, and progressive orchardists now follow this practice.

Peaches.—In the case of peaches the principal disease in California is a twig and limb blight, which practically destroyed the industry in many sections until the Department of Agriculture demonstrated that the disease could be controlled by spraying with Bordeaux mixture. In the Eastern and Southern States the principal disease of the peach is the yellows. In Michigan and New York a new disease known as "little peach" has appeared, and in all these sections, especially in the South, peach rot, caused by a fungus attacking the fruit, is very destructive. The first two diseases can be controlled by the eradication method; that is, the immediate destruction of the diseased trees and replanting. The latter disease heretofore has not been controllable, owing to the fact that the copper-spraying mixtures have been destructive to peach foliage. The recent discovery by one of the department experts that the peach rots could be controlled by self-boiled lime-sulphur mixture has marked the beginning of a new era in peach culture.

One of the principal difficulties with our cultivated varieties of peaches is probably that they are not perfectly adapted to the climatic conditions of our Eastern and Southern States. Whether improvements can be made along the line of better adaptation of varieties is still a question so far as peaches are concerned. A southwestern species closely related to the cultivated peach may possibly be of some value in this connection.

Plums.—The blood of our native plums has largely entered into the varieties adapted for culture in the various sections of the United States. The European plums and even the Japanese varieties have not proved to be well adapted to our climatic conditions and are not resistant to the diseases and insects prevalent here. Hybrids between many of these finer-fruited sorts and our native plums, however, combine the good qualities of both. There are over 200 horticultural varieties of native plums now described. While they are now largely cultivated, it is probable that the better hybrid sorts will eventually take their place.

Apples.—The apple, which appears to be fairly well adapted to our Northeastern States, is not well adapted to the severe climatic conditions of the upper Mississippi and Missouri valleys. Some seedling varieties have been developed which are superior to the ordinary cultivated sorts, but the final development of varieties adapted to this region of extremes of climate will undoubtedly come through the introduction of the blood of the native crab of that region. If the resistance, vigor, and adaptability of this native species can be combined with the good fruit qualities of the ordinary apple, an ideal variety will be produced.

Small fruits.—The total acreage of small fruits reported in the last census was 304,029 acres, valued at $25,030,877, and may fairly represent the status of this class of crops. From the commercial standpoint, the small fruits are usually classed with vegetables and truck crops and are cultivated for special markets or for canning and drying. The small amounts usually grown on most farms and often on city lots for home use are usually not reported for census enumeration, but in the aggregate amount possibly to as much as the reported area.

The small fruits of greatest importance are the strawberries, raspberries, blackberries, currants, gooseberries, and cranberries. There are a very large number of excellent varieties of all these fruits, developed largely from our native wild species. Introduced varieties were early found not to be well adapted to our conditions and were seriously affected by diseases occurring on our wild species, but to which our native species were resistant. However, in the improvement of varieties our native and introduced species have often been hybridized and the good qualities of both sorts thus combined. The strawberry, our most important small fruit, is an exception to this rule, as the species giving rise to our cultivated strains is a native of Chile, although there are a large number of good native varieties. In all the small fruits, however, there is the greatest opportunity for improvement, especially along the line of adaptation to special conditions and uses. With the increasing demands for this class of fruits improvements are gradually taking place. We have the foundation of our native species for almost unlimited development.

Grapes.—With the exception of California, the grape industry of the United States is based on our native species, the improved varieties being largely accidental seedlings. The Old Cape or Alexander grape was found wild in the woods of Pennsylvania; the Catawba was found in the woods of South Carolina; the Concord was a chance seedling in a Massachusetts garden, probably from the wild fox grape; the Worden was raised from a seed of Concord; the Delaware was probably a chance cross between a native species and a European variety, as both existed where the Delaware originated. Some very fine varieties, like the Brighton, were the result of artificial crosses. Only a very little has been done in the production of varieties for special purposes and in their general improvement. The quality of

European grapes is far superior to that of the American varieties, but the former are not adapted to our climate or resistant to our grape diseases, especially the phylloxera and black and brown rots. If the vigor and disease resistance of our native species can be bred into some of the finer European sorts, it would mean a new era for the grape culture of the Southern, Eastern, and Middle States.

In California the European varieties do fairly well, and a large industry in their culture has developed. Many of the varieties, however, are not perfectly adapted to California conditions, and the introduction of some American vigor has already been found necessary in order to obtain resistance to phylloxera, which has now gained a foothold in California, and to the California vine disease, which is very destructive to the tender European sorts.

California has over 90,500,000 vines, producing over 721,000,000 pounds of grapes, valued at over $5,500,000. These are largely of the European types. New York has over 29,500,000 vines, producing nearly 250,000,000 pounds of fruit, valued at nearly $3,000,000. Ohio has about half as much as New York, and Pennsylvania, Michigan, Illinois, Indiana, Kansas, Missouri, Georgia, Iowa, and Oklahoma have from 3,000.000 to 5,000,000 vines each.

There is a decided tendency to the overproduction of the American varieties. Even in the culture of the more resistant strains careful spraying is necessary in order to control the black and brown rots.

Subtropical fruits.—Of the subtropical fruits the principal ones are the orange, lemon, banana, pineapple, lime, citron, pomelo, guava, olive, etc. Of these the largest industry is in orange culture, California leading with about 5,500,000 trees, Florida with 2,500,000, Louisiana with 141,116, Arizona with 48,570, and smaller numbers in Texas, Mississippi, Alabama, and a few other States.

The principal lemon industry is in California, Florida, Arizona, and to a small extent in other States. The other citrus fruits are also grown in the same States.

The principal difficulty with the citrus industry arises from the effect of cold waves and heavy frosts striking the orchards during the growing season. The industry has been several times nearly destroyed in Florida and the Gulf States from this cause and has suffered seriously in some localities in California. Most of the citrus fruits cultivated in the United States are the results of what might be considered chance introductions and chance seedlings. There are many much more cold-resistant varieties of oranges in India, China, and Japan, which would doubtless prove valuable for northern Florida and the Gulf States. These introductions will be made by the Department of Agriculture. Another recourse is the crossing of the tenderer fine-fruited sorts with the cold-resistant *Citrus trifoliata*, which grows as far north as Philadelphia. From the many results of such crosses it is evident that oranges of much greater cold-resisting power can be developed. A large number of new types of citrus fruits have thus been secured, some of which are seedless and very juicy, some very sour, some moderately sour, and some fairly sweet. These are of first generation hybrids, however, and it is from the second generation that the larger number of intermediate sorts will develop. Varieties of citrus fruits for home use will undoubtedly result from such breeding work adapted for growth throughout the cotton States and the Southwest.

In the hotter sections of the Southwest where irrigation is practiced there are many areas of soil too alkaline for ordinary crops which are adapted to the date palm. About 50 varieties of the finer strains of dates have been introduced from the Old World and are found to give excellent results in this southwestern region. A profitable fruit industry can therefore be built up in soils and climate not adapted to other fruits. In the drier sections of the Southwest the dry-land olive is proving successful, and this valuable source of olive oil can undoubtedly be cultivated over large areas in Arizona and California, and possibly in New Mexico.

The pistache nut, also adapted to these dry areas, has been introduced and is proving well adapted to the region.

Similar improvements have been undertaken with the lime, the lemon, the grape fruit, the tangerine, and other species. In the case of the pineapple more than 200 new seedling varieties have been developed, some of which are far superior to any varieties now grown in the United States.

Besides these fruits there are many other tropical and subtropical fruits which are being tested in these regions and can be developed into industries of considerable importance as soon as there is demand for them.

NUTS.

Almonds.—The cultivation of almonds has developed to a considerable extent in California and Arizona, principally, however, in the former State, where over 1,500,000 trees are grown, producing nearly 7,000,000 pounds of nuts.

Cocoanuts.—Cocoanuts are produced in considerable numbers in Florida, approximately 50,000 trees being recorded in that State in the last census. This nut, however, is far more important in Cuba, Porto Rico, and the Philippines. It has recently been attacked by a serious disease, destroying in a short time many of the trees. Unless some means of control is discovered it is feared that the industry will be destroyed in all these places. The disease has not yet reached Florida or Porto Rico.

Pecans.—The pecan hickory is native in the Southern Central States, and many valuable seedling varieties are known. The nut has been planted in orchards in recent years and large quantities are thus produced. The finer varieties are now being selected and propagated by budding and grafting, so that the nut can now be said to be practically domesticated and in the process of improvement. Something over 3,000,000 pounds were produced during the last census year, about 56 per cent of which was grown in Texas. The pecan is susceptible of great improvement, and the extension of this nut industry is certain to be very great, provided the diseases which attack the cultivated orchards can be controlled.

English walnuts.—The Persian or English walnuts are cultivated to a considerable extent in southern California, where there are now nearly a million trees, producing something over 10,000,000 pounds of nuts. Not much attention has been given to varieties, so that the orchards are considerably mixed. A serious disease caused by bacteria has greatly reduced the yield, but it has been discovered that certain varieties are resistant, and it is probable that many of the orchards will be worked over to these resistant strains.

Very little attention has been given to the improvement of the great number of native nuts growing in various sections of the United States. With the increasing importance of this class of fruits it is probable that the native species will be domesticated and greatly improved in the near future.

SUMMARY.

I have now presented very briefly some of the principal facts regarding our important cultivated and native plants, and have shown that we have in all our plant resources a large number of extremely valuable varieties and sorts of local adaptation simply waiting to be utilized. Our agriculture and horticulture have been extremely primitive in the attention which has been given to seed selection, the improvement of varieties, and their adaptation to special uses. This, of course, has been the result of the rapidly expanding areas brought under cultivation and the general promiscuous and careless testing of varieties. In the past the great market demands for staple crops have given little consideration to anything but the most general qualities. Improved transportation methods have brought practically the whole world into competition, so that the cheapest and most extensive methods have necessarily prevailed. As population increases and territorial expansion decreases, the demand for more intensive methods becomes greater and more attention can be given to the improvement of cultural methods. The first step in this direction will certainly be the better utilization of our enormous plant resources.

It has been shown that by careful selection of the best individual plants, and propagating from these, the yield of all our important staple crops could easily be doubled. The means for accomplishing this already exist in our fields and gardens. For still greater improvement we can draw on cultivated and wild plants throughout the world. With the exception of the absolutely arid sections of the United States, where no rainfall or other source of water is available, there is not a foot of ground from which valuable crops can not be secured or developed, and these include grain, forage, and fruits.

Besides the great gains which can be secured by the selection and improvement of varieties of crops, the improvements in cultural methods also offer opportunities for great increase in quantity, quality, and certainty of yield. The great mass of our farmers have been as careless in their methods of agricultural production as they have in their selection of varieties. While there has been tremendous waste in following such methods, due to the rapid expansion, the close competition, and the small margin of profit, the conditions have nevertheless been the cause of the development of some of our most important mechanical methods. It has been necessary to cultivate large areas with a small amount of labor, which has led to the wonderful development of mechanical methods and improved machinery which has characterized American agriculture.

Along with the general careless methods, little attention has been given as a rule to the conservation of soil fertility. This matter has been referred to briefly in the discussion of the various crops and will not be entered into further in this paper, as it is covered by the work of another bureau. Although the larger part of the product of plant growth is taken directly or indirectly from the air, nevertheless a small but essential part comes from the soil, and it is absolutely necessary, in order to maintain the soil in a highly productive condition, to keep in it a readily available supply of the essential nutrients, especially nitrogen, phosphoric acid, and potash. The physical condition of the soil, its water-holding capacity, and its ability to absorb oxygen are controlled in a large measure by the organic matter which it contains. A high humus content is essential to a good soil. More than any other factor influencing the fertility and crop-producing power is the organic life of the soil, especially the bacteria and fungi and low organisms of this class inhabiting it. The control of the nature and quantity of these organisms present is soon to become one of the most important factors in agricultural production.

The accumulation in the soil of organisms deleterious to crop growth, resulting from continued culture to a single crop, is one of the most prolific causes of the deterioration in crop-producing power, as has been pointed out in the case of a number of our most important crops. Besides the development of resistant crops, the most important procedure will be in the adoption of crop-rotation systems which prevent the accumulation of these parasites and which enable the producer to make the proper return to the soil, by fertilization and other means, of some of the elements taken from it.

MAP NO. 3.—OAT CROP OF THE UNITED STATES, 1898-1907.

Upper figures show percentage of average annual acreage. Lower figures show percentage of average annual production.

THE OAT CROP.

By C. W. WARBURTON,

Bureau of Plant Industry, United States Department of Agriculture.

IMPORTANCE OF THE CROP.

Oats rank fifth among the farm crops of the United States in importance and value, being exceeded only by corn, hay, cotton, and wheat. The average area devoted to the production of this crop in the ten years from 1898 to 1907 has been 28,300,000 acres, while the average annual production has amounted to 841,000,000 bushels. The average annual farm value for the same period, as estimated by the Bureau of Statistics of this department, has been $265,596,000, or $9.38 to the acre. This is slightly less than the acre value of the wheat crop, $9.62, and about a dollar less than that of corn, $10.40.

The accompanying map (No. 1) shows the average annual acreage in each State for the past ten years and the average total production of each State. Map No. 2 also shows the annual acreage, with the average yield to the acre, while map No. 3 shows each State's proportion of the annual acreage and production. This last is of particular interest, as it shows the relation between acreage and production in the various States. Thus Iowa, the leading State, produces 14.45 per cent of the total crop on 13.86 per cent of the acreage, and Illinois produces nearly 14 per cent of the crop on slightly more than 13 per cent of the acreage. As extremes, Washington and Georgia may be cited, the latter producing but 0.53 per cent of the total crop on 1.12 per cent of the acreage, while the former shows 0.77 per cent on but 0.49 per cent of the total area.

REGION OF GREATEST PRODUCTION.

The production of oats is greatest in the northern Mississippi Valley, in the northern part of the region generally known as the corn belt, and in the States lying just to the north of that belt. The "oat belt" might be said to include Iowa, Illinois, Wisconsin, Minnesota, North Dakota, South Dakota, and Nebraska. In these 7 States are included 54.78 per cent of the total acreage and 58.03 per cent of the production. If the crop of Michigan, Ohio, and Indiana is added to that of the 7 States just mentioned, these figures increase relatively to 67.91 per cent and 71.4 per cent. While the crop is thus centralized it is comparatively cosmopolitan in its nature, for it is grown in every State and Territory, and in only two, Rhode Island and Arizona, is the annual crop less than 100,000 bushels, while corn falls below that figure in Montana, Wyoming, and Nevada. In 15 States, notably in New York, Wisconsin, and Minnesota, the oat crop exceeds the corn crop in value.

NEED FOR IMPROVEMENT.

While the foregoing figures show that the oat crop is very largely to be reckoned with in our farm economy, yet the partial failures in the two seasons just past, 1907 and 1908, in which unfavorable weather conditions, insects, and diseases combined to reduce the production to a point well below the ten-year average, indicate the need of a thorough study of varieties and their adaptation, methods of combating insect and fungous pests, and of seeding, fertilizing, and harvesting the crop.

VARIETAL ZONES.

No very definite divisons can be made to show the adaptability of varieties or of classes of varieties, but, roughly speaking, the States may be grouped into three zones, the southern one including Delaware, Maryland, West Virginia, Kentucky, Missouri, Kansas, and the States to the south, and extending westward through New Mexico and Arizona to California; a central belt including New Jersey, Pennsylvania, Ohio, Indiana, Illinois, Iowa, and Nebraska; and a northern one embracing New England, New York, Michigan, Wisconsin, Minnesota, the Dakotas, the Intermountain States, and the States of the Pacific Northwest. This division is inaccurate and far from satisfactory, but in general the best producing varieties or types are similar within these three divisions.

THE SOUTHERN DIVISION.

The first, or southern, division includes about 20 per cent of the total annual acreage of oats, but produces only 15 per cent of the crop. The varieties most largely grown are Rustproof, Virginia Gray, and Burt. Rustproof, often called "Texas Red" or "Texas Rustproof," is the typical and parent variety of the Rustproof group, which includes Appler, Lawson, and Culberson. This group, as usually grown, is a mixture in varying proportions of at least three varieties, the typical large-grained red oat of the true Rustproof variety, a strain with medium-sized black grains, and one with small white ones. It is probable that the red grain is the most desirable type, though very good results have been secured from the small white strain when separated from the mixture. The ordinary red type is of medium height, straw usually strong, and the grain large and reddish or yellowish brown in color. Practically all of the berries are bearded, the beards, particularly on the larger grain, being large and long. The larger grain is also provided with a number of long, bristly hairs at the base, a characteristic which distinguishes this group from the other varieties commonly grown in the South, in which the bristles are either entirely wanting, occur on only a few of the spikelets, or are much shorter than on Rustproof. The varieties of this group are, as the name indicates, resistant to rust, and are generally the most productive and satisfactory for growing in the section under discussion. They may be sown in the South either in fall or spring—in fact, at any time from September to March. In the northern part of the belt, late winter or spring sowing is generally advisable, though the fall-sown crop is usually more productive when it survives the winter.

Virginia Gray or Winter Turf is a taller, more slender variety than Rustproof, adapted to fall or early winter sowing in this region. It is rather hardier than Rustproof and is grown largely in Virginia and North Carolina, and to some extent in Kentucky, Tennessee, and the other Southern States. It is not usually successful when sown in the spring. The grain is of medium size, usually not bearded, gray or light grayish yellow. The two grains of the spikelet separate readily in thrashing, while in Rustproof they are usually quite persistent. This variety is of value where Rustproof will not withstand the winter, or where the production of hay or straw is more important than that of grain.

Burt is the only strictly spring variety of oats generally grown in the South. At present it can hardly be considered of importance outside of Kentucky and Tennessee, though it is grown to some extent in the higher portions of the other Southeastern States. This variety, sometimes known as "Ninety-Day" or "May," has more slender, lighter-colored grains than Rustproof, and the spikelets are usually without the basal hairs. It ripens earlier than Rustproof and in some sections is more productive. On account of its earliness it frequently escapes injury from fungous diseases which attack other spring-sown varieties. This variety, as well as Virginia Gray, is quite pure as ordinarily grown.

The greatest need for work on oats in the South, so far as the variety question is concerned, is the production of pure strains of Rustproof, which are winter hardy and highly productive. This should be comparatively easy to accomplish in a few years by careful selection. Other means of increasing the acre yield, and so increasing the net return, are good preparation of the seed bed, fertilization, and early seeding.

The oat crop in the South is frequently put in with little preparation, the seed sometimes being sown broadcast on cornstalk or other land and covered with a cultivator or disk harrow. Where a grain drill is available, however, it is more frequently used than is the case in the corn belt. Sowing with a grain drill not only aids in securing a uniform stand by distributing the seed evenly and covering it all to the same depth, but, in the case of fall-sown grain, the furrows left by the drill serve as a protection from the heaving caused by the alternate freezing and thawing of winter and early spring. In some sections of the South, particularly in Georgia, what is known as the "open-furrow" method of seeding is quite common. A planter similar to a cotton planter is used, the seed being drilled in the bottom of an open furrow. This furrow is left open through the winter, except as it is closed naturally by the washing of the banks and by the action of frost. This method obviates in a large measure the danger of winter damage, but is slow and expensive, as only one row can be sown at a time. A machine on the order of a grain drill, which sows several rows at once but leaves the ground more ridged than the ordinary type of that tool, is desirable for the winter oat region.

In the South, as in the North, the oat crop is ordinarily grown on the poorest land. While it is true that oats will produce relatively more on poor land than will other grain crops, yet the crop responds so readily to good treatment and fertilizers that the extra expense is justified. The use of fresh manure is not advisable as it is likely to cause a rank growth of straw, liable to lodge, at the expense of grain production. Well-rolled manure and complete fertilizers, particularly those rich in potash and phosphorus, are productive of the best results, though nitrogenous fertilizers, especially those in the form of green manures, are decidedly beneficial.

The winter oat crop is ordinarily sown in late October or November, whereas careful tests show that larger and more certain crops can be secured by seeding in September or early October. If spring seeding is necessary, it should be done as early as possible—during February in the extreme south and in March in the northern part of this belt. Spring seeding is not to be recommended, however, where there is any possibility of securing a stand from fall sowing.

The advantage of early fall seeding over later sowing is obvious. The young plants become well established before cold weather, and the growth of both top and root is often sufficient to prevent winter injury which would be serious in the late sown fields. Fall or very early spring seeding is to be recommended over late spring seeding, as it hastens maturity, i. e., the crop ripens in time to avoid much damage from unfavorable weather conditions and fungous diseases.

THE CENTRAL DIVISION.

In the central belt, which includes 47 per cent of the crop area and 48.5 per cent of the total production, oats, while largely grown, can not be considered profitable. A recent estimate by Prof. A. N. Hume, of the Illinois Experiment Station, shows that the average crop of oats in that State, 33 bushels, is produced at a loss of $3.32 per acre. However, the oat crop is a very necessary one in the common systems of rotation used in the corn belt, and is not to be discarded on the showing just quoted. Then, too, the best farmers secure yields much better than the state average, and the price, at least in recent years, is considerably higher than the 26 cents per bushel used in this calculation.

The varieties of oats grown in the central belt are too numerous for extended mention, but may be roughly divided into the small, early, yellow varieties, with rather light, slender straw, small, slender, white or yellow grain, maturing in ninety to one hundred days from sowing, and the large, medium to late varieties, taller and more rank growing with medium to large, usually white grain, maturing in one hundred to one hundred and twenty days. The latter group may be further divided into the Potato and Welcome groups, the former with short, plump grains, and the latter with longer, more pointed ones. In the first class may be included Alaska, Early Champion, Sixty-Day, and Kherson, the two latter having been imported from southern Russia about ten years ago. In the Welcome group may be included such well-known varieties as American Banner, Clydesdale, Lincoln, Silvermine, and Welcome, while in the Potato group Early Siberian, Green Mountain, Probsteier, White Schoenen, and Wideawake are to be found. The first-named group, though perhaps occupying the smallest acreage, is probably the most reliable, on account of its earliness, which enables it to escape unfavorable weather conditions and resultant attacks of fungous diseases. The chief objections to the varieties of this class are the small size of the grains and, in the case of Sixty-Day and Kherson, the yellow color. In tests at the Illinois, Iowa, and Nebraska stations, however, these two varieties have in recent years been most reliable. Early Champion is specially liable to smut attacks, and should always be treated with some one of the well-known smut preventives.

Of the Welcome group, Silvermine is perhaps the best known and most widely popular variety. The varieties of this group, however, frequently mature too late for the best results, as when sown around April 1, their ripening period, during the first two weeks of July and extending up to July 20 in the northern portion of this belt, is frequently decidedly unfavorable for the development of the oat crop. The oat crop is usually most satisfactory in cool, moist climates, and the heat of the July days in the corn belt is often disastrous, whether the weather is wet or dry. In a dry season, the grain ripens prematurely and is shriveled and light, and in a wet one, rust develops rapidly, with its resultant serious effect on the grain yield. The use of early varieties, which frequently mature before the weather conditions become unfavorable, is strongly to be recommended in the corn belt.

In the matter of soil preparation, the oat crop gets little attention. A circular of inquiry sent out to Iowa farmers showed that practically the entire oat crop was sown on corn ground, and more than 70 per cent of the farmers gave no previous preparation. The usual method is to sow the grain broadcast, then disk and harrow. In this manner it is put in at varying depths, germination extends over a considerable period, and the early growth of the crop is irregular. A considerable portion of the seed is covered so little or so much that it fails to germinate at all. Double disking and double harrowing of cornstalk land before seeding is strongly to be recommended, and sowing with a grain drill at a depth of 2 inches is desirable. In a test at the Iowa station, drilled seed yielded nearly 10 bushels more to the acre than broadcasted seed in 1907, a season of poor oat crops in that section.

Few fertilizer experiments with oats have been conducted in this section. The general belief that it is advisable to apply manure immediately preceding an oat crop is well founded, and the practice of manuring for corn and following the corn with oats is no doubt the best plan which can be devised. However, it may be well to apply some form of potash to the oat crop, for corn-belt soils are often low in available forms of this element and its addition might go far to solve the problem of weak straw and lodging.

THE NORTHERN DIVISION.

In the northern belt, where 33 per cent of the total oat acreage of the United States produced 36.5 per cent of the crop, the varieties ordinarily grown are of the same late maturing type frequently found in the section just discussed, though occasionally varieties of the early type are grown. In some sections "side" oats are the prevailing type. The varieties of this type are even later than the Potato oats. Owing to the fact that conditions here are usually more favorable during July than they are in the corn belt, late varieties are more reliable, though in some seasons they are not productive. At the Wisconsin station, Sixty-Day, a variety of the early type, and

Swedish Select, a Potato oat, are the highest yielding varieties. At the Minnesota station the leading varieties are Early Gothland, a rather early variety of the Silvermine type, and Imp. Ligowo, of the Potato type, while in South Dakota Sixty-Day and Swedish Select are prominent. In North Dakota side oats of the White Russian and Tartarian varieties are largely grown, though Sixty-Day has been a very satisfactory variety at the experiment station. In Montana and the Pacific Northwest the prevailing varieties are the late maturing Potato and side types.

General discussion of soil preparation, methods of seeding, and fertilization in the central district is also applicable here, though the more favorable weather conditions and better adapted varieties make the oat crop more commonly profitable than in the corn belt. Indeed, the oat crop is second only to wheat in this region and in some of the States is of even greater value than that grain.

The need of rotation and of cultivated crops is particularly great in some sections of this belt. In portions of Minnesota, and throughout the Dakotas and the Northwestern States, continuous cropping to wheat, barley, flax, and oats has greatly decreased the fertility of the land and increased the growth of weeds. An increased proportion of grass land and cultivated crops will check the weed nuisance, and the fertility of the land may be restored by the use of clover and other green-manuring crops, and of manure. More live stock should be kept, and the acreage of small grain should be reduced. With proper handling 3 acres will produce as much wheat or oats as 4 do now, and the remaining one-fourth of the land may be devoted to forage and live stock without reducing the grain production.

SMUT TREATMENT.

It is probable that smut annually destroys from 3 to 5 per cent of the oat crop of the United States. In certain sections, and in years favorable to smut development, the loss is much greater. A conservative estimate of 4 per cent of the annual crop would mean a loss of 34,000,000 bushels on an average crop, or a money loss on the same basis of more than $10,000,000. In view of the ease and cheapness of preventive treatment, either with formalin solution or hot water, there is no reason why this annual loss could not be almost entirely avoided.

METHODS OF HARVESTING.

While the discussion thus far has been entirely concerned with the preparation of the soil and the sowing of the crop, there is need of more attention in many sections to the methods of harvesting, particularly with regard to stacking the grain.

When properly handled the grain goes through three "sweats" or ripening processes, each of which, under suitable conditions, improves the quality. The first is in the shock, the second in the stack, and the third in the bin after thrashing. The very common practice of thrashing from the shock, a practice seemingly increasing in vogue, does away with the second sweat, and at the same time greatly increases the possibility of deterioration in quality from weather damage. The increase of cost from stacking is usually much more than balanced by the increased value of the crop over that left in the shock until thrashed.

SUMMARY.

The oat crop, which ranks fifth in importance among our farm crops, is annually valued at about $265,000,000. More than one-half of the entire crop is produced in seven States in the upper Mississippi Valley.

While immensely valuable and a very necessary crop in rotations, oats are frequently produced at a very small profit or often at a loss.

There is great need of improvement in varieties, methods of soil preparation, seeding, and harvesting to obviate this loss.

The United States can be approximately divided into three varietal zones.

The typical varieties of the southern zone are Rustproof, Virginia Gray, and Dun. The crop can be increased in the South by the selection of high producing winter strains, particularly of Rustproof, by early seeding and by the liberal use of fertilizers.

The typical varieties of the central zone are Sixty-Day, Silvermine, and White Schoenen. In this section the use of the earliest varieties, better preparation of the soil, and drilling are suggested.

In the northern belt, the region of greatest production to the acre, Tartarian, Swedish Select, Progress, and Sixty-Day are typical varieties. Better yielding strains of these varieties, better preparation of the soil, and drilling will increase the yield. Preventive treatment is essential to prevent serious loss from smut. Stacking will ordinarily increase the quality of the grain, while thrashing from the shock greatly increases the possibility of injury from bad weather.

THE ORIGIN OF CULTIVATED PLANTS.

By Alphonse De Candolle.

SUMMARY AND CONCLUSION.

[The "Summary and Conclusion," Part III of "The Origin of Cultivated Plants," by Alphonse De Candolle, is here reprinted (with some slight modifications) for convenient reference in connection with the article entitled "Agricultural Production," by A. F. Woods.]

GENERAL TABLE OF SPECIES, WITH THEIR ORIGIN AND THE EPOCH OF THEIR EARLIEST CULTIVATION.

The following table includes a few species of which a detailed account has not been given, because their origin is well known and they are of little importance.

Explanation of the signs used in the table: (1) Annual; (2) biennial; 4, perennial; 5, small shrub; 6, shrub; 7, small tree; 8, tree. The letters indicate the certain or probable date of earliest cultivation. For the species of the Old World: A, a species cultivated for more than four thousand years (according to ancient historians, the monuments of ancient Egypt, Chinese works, and botanical and philological indications); B, cultivated for more than two thousand years (indicated in Theophrastus, found among lacustrine remains, or presenting various signs, such as possessing Hebrew or Sanskrit names); C, cultivated for less than two thousand years (mentioned by Dioscorides and not by Theophrastus, seen in the frescoes at Pompeii, introduced at a known date, etc.). For American species: D, cultivation very ancient in America (from its wide area and number of varieties); E, species cultivated before the discovery of America, without showing signs of a great antiquity of culture; F, species only cultivated since the discovery of America.

Species native to the Old World.

CULTIVATED FOR THE SUBTERRANEAN PARTS.

Name and duration.	Date.	Origin.
Radish—Raphanus sativus (1)	B.	Temperate Asia.[a]
Horse-radish—Cochlearia armoracia 4	C.	Eastern temperate Europe.
Turnip—Brassica rapa (2)	A.	Europe; western Siberia (2).
Rape—Brassica napus (2)	A.	Europe; western Siberia (?).
Carrot—Daucus carota (2)	B.	Europe; western temperate Asia (?).
Parsnip—Pastinaca sativa (2)	C.	Central and southern Europe.
Tuberous chervil—Chærophyllum bulbosum (2)	C.	Central Europe; Caucasus.
Skirret—Sium sisarum 4	C.	Altaic Siberia; northern Persia.
Madder—Rubia tinctorum 4	B.	Western temperate Asia; southeast of Europe.
Salsify—Tragopogon porrifolium (2)	C. (?)	Southeast of Europe; Algeria.
Scorzonera—Scorzonera hispanica	C.	Southwest of Europe; south of the Caucasus.
Rampion—Campanula rapunculus (2)	C.	Temperate and southern Europe.
Beet—Beta vulg. (2) 4 Vegetable	B.	Canaries; Mediterranean basin; western temperate Asia.
Root	B.	A result of cultivation.
Garlic—Allium sativum 4	B.	Desert of the Kirghis, in western temperate Asia.

[a] Doctor Bretschneider writes to me from Peking, December 22, 1882, that the species is mentioned in the Ryd, a work of the year 1100 B. C. I do not know if we must suppose the original habitat to be China or western Asia.

Species native to the Old World—Continued.

CULTIVATED FOR THE SUBTERRANEAN PARTS—Continued.

Name and duration.	Date.	Origin.
Onion—Allium cepa (2)	A.	Persia; Afghanistan; Beluchistan; Palestina(?).
Welsh onion—Allium fistulosum 4	C.	Siberia (from the land of the Kirghis of Baikal).
Shallot—Allium ascolonicum 4	C.	Modification of A. cepa (?) unknown to wild.
Rocambole—Allium scorodoprassum 4	C.	Temperate Europe.
Chives—Allium schaenoprasum 4	C. (?)	Temperate and northern Europe; Siberia, Khamschatka; North America (Lake Huron).
Taro—Colocasia antiquorum 4	B.	India; Malay Archipelago; Polynesia.
Apé—Alocasia macrorrhiza 4	(?)	Ceylon; Malay Archipelago; Polynesia.
Konjak—Amorphophallus konjak 4	(?)	Japan (?)
Yams—Dioscorea sativa 4	B. (?)	Southern Asia (especially Malabar) (?); Ceylon (?); (Java) (?).
Dioscorea Batatas 4	B. (?)	China (?)
Dioscorea japonica 4	(?)	Japan (?)
Dioscorea alata 4	(?)	East of the Asiatic Archipelago.

CULTIVATED FOR THE STEMS OR LEAVES.

1. VEGETABLES.

Cabbage—Brassica oleracea (1), (2), 5, 7	A.	Europe.
Chinese cabbage—Brassica chinensis (2)	(?)	China (?); Japan (?).
Water cress—Nasturtium officinale 4	(?)	Europe; northern Asia.
Garden cress—Lepidium sativum (1)	B.	Persia (?).
Sea kale—Crambe maritima 4	C.	Western temperate Europe.
Purslane—Portulaca oleracea (1)	A.	From the western Himalayas to southern Russia and Greece.
New Zealand spinach—Tetragonia expansa (1)	C.	New Zealand and New Holland.
Garden celery—Apium graveolens (2)	B.	Temperate and southern Europe; northern Africa; western Asia.
Chervil—Anthriscus cerefolium (1)	C.	Southeast of Russia; western temperate Asia.
Parsley—Petroselium sativum (2)	C.	Southern Europe; Algeria; Lebanon.
Alexanders—Smyrnium olus-atrum (2)	C.	Southern Europe; Algeria; western temperate Asia.
Corn salad—Valerianella olitoria (1)	C.	Sardinia, Sicily.
Cardoon	C.	Southern Europe; northern Africa; Canaries; Madeira.
Artichoke—Cyuara Cardunculus (2) 4 {Cardoon Artichoke.	C.	Derived from the cardoon.
Lettuce—Latuca scariola (1) (2)	B.	Southern Europe; northern Africa; western Asia.
Wild chicory—Cichorium Intybus 4	C.	Europe; northern Africa; western temperate Asia.
Endive—Cichorium Endivia (1)	C.	Mediterranean basin; Caucasus; Turkestan.
Spinach—Spinacia oleracea (1)	C.	Persia (?).
Orach—Atriplex hortensis (1)	C.	Northern Europe and Siberia.
Amaranth—Amarantus gangeticus (1)	(?)	Tropical Africa; India (?).
Sorrel—Rumex acetosa (1) 4	(?)	Europe; northern Asia; mountains of India.
Patience dock—Rumex patientia 4	(?)	Turkey in Europe; Persia.
Asparagus—Asparagus officinalis 4	B.	Europe; western temperate Asia.
Leek—Allium ampeloprasum 4	B.	Mediterranean basin.

2. FODDER.

Lucern—Medicago sativa 4	B.	Western temperate Asia.
Sainfoin—Onobrychis sativa 4	C.	Temperate Europe; south of the Caucasus.
French honeysuckle—Hedysarum coronarium 4	C.	Center and west of the Mediterranean basin.
Purple clover—Trifolium pratense 4	C.	Europe; Algeria; western temperate Asia.
Alsike clover—Trifolium hybridum (1)	C.	Temperate Europe.
Italian clover—Trifolium incarnatum (1)	C.	Southern Europe.
Egyptian clover—Trifolium alexandrinum (1)	C.	Syria; Anatolia.
Ervilia—Ervum Ervilia (1)	B.	Mediterranean basin.
Vetch—Vicia sativa (1)	B.	Europe; Algeria; south of the Caucasus.
Flat-podded pea—Lathyrus Cicera (1)	B.	From Spain and Algeria to Greece.
Chickling vetch—Lathyrus sativus (1)	B.	South of Caucasus.
Ochrus—Lathyrus ochrus (1)	B.	Italy; Spain.
Fenugreek—Trigonella fœnumgræcum (1)	B.	Northeast of India and western temperate Asia.
Bird's-foot—Ornithopus sativus (1)	B. (?)	Portugal; south of Spain; Algeria.
Nonsuch—Medicago lupulina (1) (2)	C.	Europe; north of Africa (?); temperate Asia.
Corn spurry—Spergula arvensis (1)	B. (?)	Europe.
Guinea grass—Panicum maximum 4	C. (?)	Tropical Africa.

Species native to the Old World—Continued.

CULTIVATED FOR THE STEMS OR LEAVES—Continued.

3. VARIOUS USES.

Name and duration.	Date.	Origin.
Tea—Thea sinensis 6	A.	Assam; China; Manchuria.
Flax anciently cultivated—Linum angustifolium 4 (2) (1).	A.	Mediterranean basin.
Flax now cultivated—Linum usitatissimum (1).	A. (?)	Western Asia (?); derived from the preceding (?).
Jute—Corchorus capsularis (1)	C. (?)	Java; Ceylon.
Jute—Corchorus olitorius (1)	C. (?)	Northwest of India; Ceylon.
Sumach—Rhus coriaria 6	C.	Mediterranean basin; western temperate Asia.
Khat—Celastrus edulis 6	(?)	Abyssinia; Arabia (?).
Indigo—Indigofera tinctoria 6	B.	India (?).
Silver indigo—Indigofera argentea 6	(?)	Abyssinia; Nubia; Kordofan; Sennaar; India (?).
Henna—Lawsonia alba 6	A.	Western tropical Asia; Nubia (?).
Blue gum—Eucalyptus globulus 8	C.	New Holland.
Cinnamon—Cinnamonum zeylanicum 7	C.	Ceylon; India.
China grass—Boehmeria nivea 4, 6	(?)	China; Japan.
Hemp—Cannabis sativa (1)	A.	Dahuria; Siberia.
White mulberry—Morus alba 7	A. (?)	India; Mongolia.
Black mulberry—Morus nigra 7	B. (?)	Armenia; northern Persia.
Sugar cane—Saccharum officinarum 7	B.	Cochin China (?); southwest of China.

CULTIVATED FOR THE FLOWERS OR THEIR ENVELOPES.

Name and duration.	Date.	Origin.
Clove—Carophyllus aromaticus 7	(?)	Moluccas.
Hop—Humulus lupulus 4	C.	Europe; western temperate Asia; Siberia.
Carthamine—Carthamus tinctorius (1)	A.	Arabia (?).
Saffron—Crocus sativus 4	A.	Southern Italy; Greece; Asia Minor.

CULTIVATED FOR THE FRUITS.

Name and duration.	Date.	Origin.
Shaddock—Citrus decumana 8	B.	Pacific Islands, to the east of Java.
Citron, lemon—Citrus medica 7	B.	India.
Bitter orange—Citrus aurantium bigardia 7	B.	East of India.
Sweet orange—Citrus aurantium sinense 7	C.	China and Cochin China.
Mandarin—Citrus nobilis 7	(?)	Do.
Mangosteen—Garcinia mangostana 7	(?)	Sunda Islands; Malay Peninsula.
Ochro—Hibiscus esculentus (1)	C.	Tropical Africa.
Vine—Vitis vivifera 6	A.	Western temperate Asia; Mediterranean basin.
Common jujube—Zizyphus vulgaris 6	B.	China.
Lotus jujube—Zizyphus lotus 6	(?)	Egypt to Morocco.
Indian jujube—Zizyphus jujuba 6	A. (?)	Burma; India.
Mango—Mangifera indica 6	A. (?)	India.
Tahiti apple—Spondias dulcis 6	(?)	Society, Friendly, and Fiji Isles.
Raspberry—Rubus idaeus 6	C.	Temperate Europe and Asia.
Strawberry—Fragaria vesca 6	C.	Temperate Europe and western Asia; east of North America.
Bird cherry—Prunus avium 8	B.	Western temperate Asia; temperate Europe.
Common cherry—Prunus cerasus 7	B.	From the Caspian to western Anatolia.
Plum—Prunus domestica 7	B.	Anatolia; south of the Caucasus; north of Persia.
Plum—Prunus insititia 6	(?)	Southern Europe; Armenia; south of the Caucasus; Talysch.
Apricot—Prunus Armeniaca 7	A.	China.
Almond—Amygdalus communis 7	A.	Mediterranean basin; western temperate Asia.
Peach—Amygdalus persica 7	A.	China.
Common pear—Pyrus communis 8	A.	Temperate Europe and Asia.
Chinese pear—Pyrus sinensis 7	(?)	Mongolia; Manchuria.
Apple—Pyrus malus 7	A.	Europe; Anatolia; south of the Caucasus.
Quince—Cydonia vulgaris 7	A.	North of Persia; south of the Caucasus; Anatolia.
Loquat—Eriobotrya japonica 7	(?)	Japan.
Pomegranate—Punica granatum 8	A.	Persia; Afghanistan; Beluchistan.
Rose apple—Jambosa vulgaris 7	B.	Malay Archipelago; Cochin China; Burma; northeast of India.
Malay apple—Jambosa malaccensis 7	B.	Malay Archipelago; Malacca.
Bottle gourd—Cucurbita lagenaria (1)	C.	India; Moluccas; Abyssinia.
Spanish gourd—C. maxima (1)	C. (?)	Guinea.
Melon—Cucumis melo (1)	C.	India; Beluchistan; Guinea.
Watermelon—Citrullus vulgaris (1)	A.	Tropical Africa.
Cucumber—Cucumis sativus (1)	A.	India.
West Indian gherkin—Cucumis anguria (1)	C. (?)	Tropical Africa.(?)
White gourd-melon—Benincasa hispida (1)	(?)	Japan; Java.
Towel gourd—Luffa cylindrica (1)	C.	India.
Angular luffa—Luffa acutangula (1)	C.	India; Malay Archipelago.

Species native to the Old World—Continued.

CULTIVATED FOR THE FRUITS—Continued.

Name and duration.	Date.	Origin.
Snake gourd—Trichosanthes anguina (1)	C.	India.(?)
Gooseberry—Ribes grossularia 5	C.	Temperate Europe; north of Africa; Caucasus; western Himalayas.
Red currant—Ribis rubrum 5	C.	Northern and temperate Europe; Siberia; Caucasus; Himalayas; northeast of the United States.
Black currant—Ribis nigrum 5	C.	Northern and central Europe; Armenia; Siberia; Manchuria; western Himalayas.
Kaki—Diospyros Kaki 7	(?)	Japan; northern China.
Date plum—Diospyros lotos 7	(?)	China; India; Afghanistan; Persia; Armenia; Anatolia.
Olive—Olea europea 7	A.	Syria; southern Anatolia and neighboring Islands.
Aubergine—Solanum melongena (1)	A.	India.
Fig—Ficus carica 7	A.	Center and south of the Mediterranean basin, from Syria to the Canaries.
Breadfruit—Artocarpus incisa 8	(?)	Sunda Isles.
Jack fruit—Artocarpus integrifolia 8	B.	India.
Date palm—Phoenix dactylifera 8	A.	Western Asia and Africa from the Euphrates to the Canaries.
Banana—Musa sapientum 7	A.	Southern Asia.
Oil palm—Elaeis guineensis 8	(?)	Guinea.

CULTIVATED FOR THE SEEDS.

1. NUTRITIVE.

Litchi—Nephelium Litchi 7	(?)	Southern China; Cochin China.
Longan—Nephelium longana 7	(?)	India; Pegu.
Rambutan—Nephelium lappaceum 7	(?)	Do.
Pistachio—Pistacia vera 6	C.	Syria.
Bean—Fava vulgaris (1)	A.	South of the Caspian (?).
Lentil—Ervum lens (1)	A.	Western temperate Asia; Greece; Italy.
Chick-pea—Cicer arietinum (1)	A.	South of the Caucasus and of the Caspian.
Lupin—Lupinus albus (1)	B.	Sicily; Macedonia; south of the Caucasus.
Egyptian lupin—Lupinus termis (1)	A.	From Corsica to Syria.
Field pea—Pisum arvense (1)	(?)	Italy.
Garden pea—Pisum sativum (1)	B.	From the south of the Caucasus to Persia (?); north India (?).
Soy—Dolichos soja (1) 6	A.	Cochin China; Japan; Java.
Pigeon pea—Cajanus indicus	C.	Equatorial Africa.
Carob—Ceratonia siliqua 8	A. (?)	Southerncoast of Anatolia; Syria; Cyrenaica (?).
Moth—Phaseolus aconitifolius (1)	C.	India.
Three-lobed kidney bean—Phaseolus trilobus4(1)	B.	India; tropical Africa.
Green gram—Phaseolus mungo 1 (1)	B. (?)	India.
Wali—Phaseolus lablab (1)	C.	Do.
Lubia—Phaseolus lubia (1)	C.	Western Asia (?).
Bambarra ground nut—Voandzeia subterranea (1)	(?)	Intertropical Africa.
Buckwheat—Fagopyrum esculentum (1)	C.	Manchuria; central Siberia.
Tartary buckwheat—Fagopyrum tartaricum (1).	C.	Tartary; Siberia to Dahuria.
Notch-seeded buckwheat—Fagopyrum emarginatum (1).	(?)	Western China; eastern Himalayas.
Kiery—Amarantus frumentaceus (1)	(?)	India.
Chestnut—Castanea vulgaris 4	(?)	From Portugal to the Caspian Sea; eastern Algeria. Varieties: Japan; North America.
Wheat—Triticum vulgare and varieties (?) (1)	A.	Region of the Euphrates.
Spelt—Triticum spelta (1)	A.	Derived from the preceding (?).
One-grained wheat—Triticum monococcum (1)	(?)	Servia; Greece; Anatolia (if the identity with the Triticum boeóticum be admitted).
Two-rowed barley—Hordeum distichon (1)	A.	Western temperate Asia.
Common barley—Hordeum vulgare (1)	(?)	Derived from the preceding (?).
Six-rowed barley—Hordeum hexastichon (1)	A.	Do.
Rye—Secale cereale (1)	B.	Eastern temperate Europe (?).
Common oats—Avena sativa (1)	B.	Do.
Eastern oats—Avena orientalis (1)	C. (?)	Western Asia (?).
Common millet—Panicum miliaceum (1)	A.	Egypt; Arabia.
Italian millet—Panicum italicum (1)	A.	China; Japan; Indian Archipelago (?).
Sorghum—Holcus sorghum (1)	A.	Tropical Africa (?).
Sweet sorghum—Holcus saccharatus (1)	(?)	Do.
Coracan—Eleusine coracana (1)	B.	India.
Rice—Oryza sativa (1)	A.	India; southern China (?).

Species native to the Old World—Continued.

CULTIVATED FOR THE SEEDS—Continued.

2. VARIOUS USES.

Name and duration.	Date.	Origin.
Poppy—Papaver somniferum (1)	B.	Derived from P. setiferum of the Mediterranean basin.
White mustard—Sinapis alba 1	B.	Temperate and southern Europe; north of Africa; western temperate Asia.
Black mustard—Sinapis nigra 1	B.	
Gold of pleasure—Camelina sativa (1)	B. (?)	Temperate Europe; Caucasus; Siberia.
Herbaceous cotton—Gossypium herbaceum 5 (1).	B.	India.
Tree cotton—Gossypium arboreum 6	B. (?)	Upper Egypt.
Arabian coffee—Coffea arabica 7	C.	Tropical Africa; Mosambique; Abyssinia; Guinea.
Liberian coffee—Coffea liberica 8	C.	Guinea; Angola.
Sesame—Sesamum indicum (1)	A.	Sunda Isles.
Nutmeg—Myristica fragrans 7	B.	Moluccas.
Castor-oil plant—Ricinus communis 6	A.	Abyssinia; Sennaar; Kordofan.
Walnut—Juglans regia 8	(?)	Eastern temperate Europe; temperate Asia.
Black pepper—Piper nigrum 6	B.	India.
Long pepper—Piper longum 5	B.	Do.
Medicinal pepper—Piper officinalis 5	B.	Malay Archipelago.
Betel pepper—Piper betle 6	B.	Do.
Areca nut—Areca catechu 7	B.	Do.
Cocoa nut—Cocos nucifera 3	(?)	Malay Archipelago (?); Polynesia (?)

Species of American origin.

CULTIVATED FOR THE UNDERGROUND PARTS.

Arracacha—Arracacha esculenta (1) 4	E.	New Granada (?).
Jerusalem artichoke—Helianthus tuberosus 4	E. (?)	North America (Indiana).
Potato—Solanum tuberosum 4	E.	Chili; Peru (?).
Sweet potato—Convolvulus batatas 4	D.	Tropical America (where?).
Manioc—Manihot utilissima 6	E.	East of tropical Brazil.
Arrowroot—Maranta arundinacea 7	(?)	Tropical (continental?) America.
Maté—Ilex paraguariensis 7	D.	Paraguay and western Brazil.
Coca—Erythroxylon coca 7	D.	East of Peru and Bolivia.
Quinine—Cinchona calisaya 7	F.	Bolivia; southern Peru.
Crown bark—Cinchona officinalis	F.	Ecuador (province of Loxa).
Red cinchona bark—Cinchona succirubra 7	F.	Ecuador (province of Cuenca).
Tobacco—Nicotiana tabacum (1)	D.	Ecuador and neighboring countries.
Nicotiana rustica (1)	E.	Mexico (?); Texas (?); California (?).
American aloe—Agave americana 7	E.	Mexico.

CULTIVATED FOR THE FRUITS.

Sweet sop—Anona squamosa 7	(?)	West India Isles.
Sour sop—Anona muricana	(?)	Do.
Custard apple—Anona reticulata 7	(?)	West India Isles; New Granada.
Chirimoya—Anona cherimolia 7	E.	Ecuador; Peru (?).
Mammee apple—Mammea americana 8	(?)	West India Isles.
Cashew nut—Anacardium occidentale 8	(?)	Tropical America.
Virginian strawberry—Fragaria virginiana 4	F.	Temperate North America.
Chile strawberry—Fragaria chiloensis 4	F.	Chile.
Guava—Psidium guayava 7	E.	Continental Tropical America.
Pumpkin and squash—Cucurbita pepo and Melopepo (1).	E.	Temperate North America.
Prickly pear—Optunia ficus indica 7	E.	Mexico.
Chocho—Sachium edule (1)	E.	Mexico (?); Central America.
Star apple—Chrysophyllum cainito 7	E.	West India Isles; Panama.
Caimito—Lucuma caimito 7	E.	Peru.
Marmalade plum—Lucuma mammosa 7	E.	Valley of the Orinoco.
Sapodilla—Sapota achras 7	E.	Campeachy; Isthmus of Panama; Venezuela.
Persimmon—Diospyros virginiana 7	F.	Eastern States of America.
Annual capsicum—Capsicum annum (1)	E.	Brazil (?).
Shrubby capsicum—Capsicum frutescens 6	E.	From the east of Peru to Bahia.
Tomato—Lycopersicum esculentum (1)	E.	Peru.
Avocado pear—Persea gratissima 8	E.	Mexico.
Papaw—Papaya vulgaris 7	E.	West Indies; Central America.
Pineapple—Ananassa sativa 4	E.	Mexico; Central America; Panama; New Granada; Guiana (?); Bahia (?).

Species of American origin—Continued.

CULTIVATED FOR THE SEEDS.

1. Nutritious.

Name and duration.	Date.	Origin.
Cacao—Theobroma cacao 7	D.	Amazon and Orinoco valleys; Panama (?); Yucatan (?).
Sugar bean—Phaseolus lunatus 4	E.	Brazil.
Quinoa—Chenopodium quinoa 1	E.	New Granada; Peru (?); Chile (?).
Maize—Zea mays (1)	D.	New Granada (?).

2. Various Uses.

Name and duration.	Date.	Origin.
Arnotto—Bixa orellana	D.	Tropical America.
Barbados cotton—Gossypium barbadense 8	(?)	New Granada (?); Mexico (?); West Indies.
Earthnuts—Arachis hypogæa (1)	E.	Brazil.
Madia—Madia sativa (1)	E.	Chile; California.

CRYPTOGRAM CULTIVATED FOR THE WHOLE PLANT.

Name and duration.	Date.	Origin.
Mushroom—Agaricus campestris 4	C.	Northern Hemisphere.

Species of unknown or entirely uncertain origin.—Common haricot—Phaseolus vulgaris (1); Musk gourd—Cucurbita moschata (1); Fig-leaved gourd—Cucurbita ficifolia.

GENERAL OBSERVATIONS AND CONCLUSIONS.

REGIONS WHERE CULTIVATED PLANTS ORIGINATED.

In the beginning of the nineteenth century the origin of most of our cultivated species was unknown. Linnæus made no efforts to discover it, and subsequent authors merely copied the vague or erroneous expressions by which he indicated their habitations. Alexander von Humboldt expressed the true state of the science in 1807 when he said: "The origin, the first home of the plants most useful to man, and which have accompanied him from the remotest epochs, is a secret as impenetrable as the dwelling of all our domestic animals. * * * We do not know what region produced spontaneously wheat, barley, oats, and rye. The plants which constitute the natural riches of all the inhabitants of the Tropics, the banana, the papaw, the manioc, and maize, have never been found in a wild state. The potato presents the same phenomenon."[a]

At the present day, if a few cultivated species have not yet been seen in a wild state, this is not the case with the immense majority. We know at least, most frequently, from what country they first came. This was already the result of my work of 1855, with modern and more extensive research has confirmed in almost all points. This research has been applied to 247 species,[b] cultivated on a large scale by agriculturists or in kitchen gardens and orchards. I might have added a few rarely cultivated or but little known, or of which the cultivation has been abandoned, but the statistical results would be essentially the same.

Out of the 247 species which I have studied, the Old World has furnished 199, America 45, and 3 are still uncertain.

---

[a] Essai sur la Geographie des plantes, p. 28.

[b] Counting two or three forms which are perhaps rather very distinct races.

No species was common to the tropical and austral regions of the two hemispheres before cultivation. *Allium schoenoprasum*, the hop (*Humulus lupulus*), the strawberry (*Fragaria vesca*), the currant (*Ribis rubrum*), the chestnut (*Castanea vulgaris*), and the mushroom (*Agaricus campestris*) were common to the northern regions of the Old and New Worlds. I have reckoned them among the species of the Old World, since their principal habitation is there and there they were first cultivated.

A great number of species originated at once in Europe and western Asia, in Europe and Siberia, in the Mediterranean basin and western Asia, in India and the Asiatic Archipelago, in the West Indies and Mexico, in these two regions and Colombia, in Peru and Brazil, or in Peru and Colombia, etc., etc. They may be counted in the table. This is a proof of the impossibility of subdividing the continents and of classing the islands in well-defined natural regions. Whatever be the method of division, there will always be species common to two, three, four, or more regions, and others confined to a small portion of a single country. The same facts may be observed in the case of uncultivated species.

A noteworthy fact is the absence in some countries of indigenous cultivated plants. For instance, we have none from the Arctic or Antarctic regions, where, it is true, the floras consist of but few species. The United States, in spite of their vast territory, which will soon support hundreds of millions of inhabitants, only yield, as nutritious plants worth cultivating, the Jerusalem artichoke and the gourds. *Zizana æquatica*, which the natives gathered wild, is a grass too inferior to our cereals and to rice to make it worth the trouble of planting it. They had a few bulbs and edible berries, but they have not tried to cultivate them, having early received the maize, which was worth far more.

Patagonia and the Cape have not furnished a single species. Australia and New Zealand have furnished one tree, *Eucalyptus globulus*, and a vegetable, not very nutritious, the *Tetragonia*. Their floras were entirely wanting in graminæ similar to the cereals, in leguminous plants with edible seeds, in Cruciferæ with fleshy roots.[a] In the moist tropical region of Australia, rice and *Alocasia macrorrhiza* have been found wild, or perhaps naturalized, but the greater part of the country suffers too much from drought to allow these species to become widely diffused.

In general, the austral regions had very few annuals, and among their restricted number none offered evident advantages. Now annual species are the easiest to cultivate. They have played a great part in the ancient agriculture of other countries.

In short, the original distribution of cultivated species was very unequal. It had no proportion with the needs of man or the extent of territory.

NUMBER AND NATURE OF CULTIVATED SPECIES AT DIFFERENT EPOCHS.

The species marked A in the table on pages 437-446 must be regarded as of very ancient cultivation. They are 44 in number. Some of the species marked B are probably as ancient, though it is impossible to prove it. The five American species marked D are especially plants provided with roots, seeds, and fruits proper for the food of man. Afterwards come a few species having fruits agreeable to the taste, or textile, tinctorial, oil-producing plants, or yielding drinks by infusion or fermentation. There are among these only two green vegetables and no fodder. The orders which predominate are the Cruciferæ, Leguminosæ, and Graminaceæ.

---

[a] See the list of the useful plants of Australia by Sir J. Hooker, Flora Tasmania, p. cx.; and Bentham, Flora Australiensis, vii, p. 156.

The number of annuals is twenty-two out of the forty-four, or 50 per cent. Out of five American species marked D, two are annuals. In the category A there are two biennials, and D has none. Among all the Phanerogams the annuals are not more than 50 per cent, and the biennials 1 or at most 2 per cent. It is clear that at the beginning of civilization plants which yield an immediate return are most prized. They offer, moreover, this advantage, that their cultivation is easily diffused or increased, either because of the abundance of seed or the same species may be grown in summer in the North, and in winter or all the year round in the Tropics.

Herbaceous perennial plants are rare in categories A and D. They are only from 2 to 4 per cent, unless we include *Brassica oleracea* and the variety of flax which is usually perennial (*L. angustifolium*), cultivated by the Swiss lake dwellers. In nature, herbaceous perennials constitute about 40 per cent of the Phanerogams.[a]

A and D include twenty ligneous species out of forty-nine, that is about 41 per cent. They are in the proportion of 43 per cent of the Phanerogams.

Thus the earliest husbandmen employed chiefly annuals or biennials, rather fewer woody species, and far fewer herbaceous perennials. These differences are due to the relative facility of cultivation and the proportion of the evidently useful species in each division.

The species of the Old World marked B have been in cultivation for more than two thousand years, but perhaps some of them belong to category A. The American species marked E were cultivated before the discoveries of Columbus, perhaps for more than two thousand years. Many other species marked "(?)" in the table date probably from an ancient epoch, but as they chiefly exist in countries without a literature and without archæological records, we do not know their history. It is useless to insist upon such doubtful categories; on the other hand, the plants which we know to have been first cultivated in the Old World less than two thousand years ago, and in America since its discovery, may be compared with plants of ancient cultivation.

These species of modern cultivation number 61 in the Old World, marked C, and 6 in America, marked F; 67 in all.

Classed according to their duration, they number 37 per cent annuals, 7 to 8 per cent biennials, 33 per cent herbaceous perennials, and 22 to 23 per cent woody species.

The proportion of annuals or biennials is also here larger than in the whole number of plants, but it is not so large as among species of very ancient cultivation. The proportions of perennials and woody species are less than in the whole vegetable kingdom, but they are higher than among the species A of very ancient cultivation.

---

[a] The proportions which I give for the Phanerogams collectively are based upon an approximative calculation made with the aid of the first 200 pages of Steudel's Nomenclator. They are justified by the comparison with several floras.

The plants cultivated for less than two thousand years are chiefly artificial fodders, which the ancients scarcely knew; then bulbs, vegetables, medicinal plants (Cinchonas), plants with edible fruits, or nutritious seeds (buckwheats), or aromatic seeds (coffee).

Men have not discovered and cultivated within the last two thousand years a single species which can rival maize, rice, the sweet potato, the potato, the breadfruit, the date cereals, millets, sorghums, the banana, and soy. These date from three, four, or five thousand years, perhaps even in some cases six thousand years. The species first cultivated during the Græco-Roman civilization and later nearly all answer to more varied or more refined needs. A great dispersion of the ancient species from one country to another took place, and at the same time a selection of the best varieties developed in each species. The introductions within the last two thousand years took place in a very irregular and intermittent manner. I can not quote a single species cultivated for the first time after that date by the Chinese, the great cultivators of ancient times. The peoples of southern and western Asia innovated in a certain degree by cultivating the buckwheats, several cucurbitaceæ, a few alliums, etc. In Europe the Romans and several peoples in the Middle Ages introduced the cultivation of a few vegetables and fruits and that of several fodders. In Africa a few species were then first cultivated separately. After the voyages of Vasco di Gama and of Columbus a rapid diffusion took place of the species already cultivated in either hemisphere. These transports continued during three centuries without any introduction of new species into cultivation. In the two or three hundred years which preceded the discovery of America and the two hundred which followed, the number of cultivated species remained almost stationary. The American strawberries, *Diospyros virginiana*, sea kale, and *Tetragonia expansa*, introduced in the eighteenth century, have but little importance. We must come to the middle of the present century to find new cultures of any value from the utilitarian point of view, such as *Eucalyptus globulus* of Australia and the *Cinchonas* of South America.

The mode of introduction of the latter species shows the great change which has taken place in the means of transport. Previously the cultivation of a plant began in the country where it existed, whereas the Australian *Eucalyptus* was first planted and grown in Algeria, and the *Cinchonas* of America in the south of Asia. Up to our own day botanical or private gardens had only diffused species already cultivated somewhere; now they introduce absolutely new cultures. The royal garden at Kew is distinguished in this respect, and other botanical gardens and acclimatization societies in England and elsewhere are making similar attempts. It is probable that tropical countries will greatly benefit by this in the course of a century. Others will also find their advantage from the growing facility in the transport of commodities.

When a species has been once cultivated it is rarely, perhaps never, completely abandoned. It continues to be here and there cultivated in backward countries or those whose climate is especially favorable. I have passed over some of these species which are nearly abandoned, such as dyer's woad (*Isatis tinctoria*), mallow (*Malva sylvestris*), a vegetable used by the Romans, and certain medicinal plants formerly much used, such as fennel, cummin, etc.; but it is certain that they are still grown in some places.

The competition of species causes the cultivation of some to diminish, of others to increase; besides, vegetable dyes and medicinal plants are rivaled by the discoveries of chemists. Woad, madder, indigo, mint, and several simples must give way before the invasion of chemical products. It is possible that men may succeed in making oil, sugar, and flour, as honey, butter, and jellies are already made, without employing organic substances. Nothing, for instance, would more completely change agricultural conditions than the manufacture of flour from its own inorganic elements. In the actual state of science there are still products which will be more and more required of the vegetable kingdom; these are textile substances, tan, india rubber, gutta-percha, and certain spices. As the forests where these are found are gradually destroyed, and these substances are at the same time more in demand, there will be the greater inducement to cultivate certain species.

These usually belong to tropical countries. It is in these regions also, particularly in South America, that fruit trees will be more cultivated—those of the order Anonaceæ, for instance, of which the natives and botanists already recognize the value. Probably the number of plants suitable for fodder and of forest trees which can live in hot, dry countries will be increased. The additions will not be numerous in temperate climates, nor especially in cold regions.

From these data and reflections it is probable that at the end of the nineteenth century men will cultivate on a large scale and for use about 300 species. This is a small proportion of the 120,000 or 140,000 in the vegetable kingdom; but in the animal world the proportion of creatures subject to the will of man is far smaller. There are not perhaps more than 200 species of domestic animals—that is, reared for our use—and the animal kingdom reckons millions of species. In the great class of molluscs the oyster alone is cultivated, and in that of the Articulata, which counts ten times more species than the vegetable kingdom, we can only name the bee and two or three silk-producing insects. Doubtless the number of species of animals and vegetables which may be reared or cultivated for pleasure or curiosity is very large—witness menageries and zoological and botanical gardens—but I am only speaking here of useful plants and animals in general and customary employment.

CULTIVATED PLANTS KNOWN OR NOT KNOWN IN A WILD STATE.

Science has succeeded in discovering the geographical origin of nearly all cultivated species; but there is less progress in the knowledge of species in a natural state—that is, wild, far from cultivation and dwellings. There are species which have not been discovered in this condition and others whose specific identity and truly wild condition are doubtful.

In the following enumeration I have classed the species according to the degree of certainty as to the wild character, and the nature of the doubts where such exist.[a]

---

[a] The species in italics are of very ancient cultivation (A or D); those marked with an asterisk have been less than two thousand years in cultivation (C or F).

1. Spontaneous species—that is, wild—seen by several botanists far from dwellings and cultivation, with every appearance of indigenous plants, and under a form identical with one of the cultivated varieties. These are the species which are not enumerated below; they are 169 in number.

Among these 169 species 31 belong to the categories A and D, of very ancient cultivation, 56 have been in cultivation less than two thousand years, C, and the others are of modern or unknown date.

2. Seen and gathered in the same conditions, but by a single botanist in a single locality. Three species: Cucurbita maxima, *Faba vulgaris*, *Nicotiana Tabacum*.

3. Seen and mentioned but not gathered in the same conditions by one or two authors and botanists, more or less ancient, who may have been mistaken. Two species: *Carthamus tinctorius*, *Triticum vulgare*.

4. Gathered wild by botanists in several localities under a form slightly different to those which are cultivated, but which most authors have no hesitation in classing with the species. Four species: *Olea europæa*, *Oryza sativa*, Solanum tuberosum, *Vitis vinifera*.

5. Wild, gathered by botanists in several localities under forms considered by some botanists as constituting different species, while others treat them as varieties. Fifteen species: Allium ampeloprasum porrum, Cichorium Endivia, var. *Crocus sativus*, var., *Cucumis melo, Cucurbita Pepo, Helianthus tuberosus, Latuca scariola sativa, *Linum usitatissimum annuum*, Lycopersicum esculentium, Papaver somniferum, Pyrus nivalis var., *Ribis grossularia, Solanum Melongena, Spinacia oleracea var., Triticum monococcum.

6. Subspontaneous—that is, half-wild—similar to one or other of the cultivated forms, but possibly plants escaped from cultivation, judging from the locality. Twenty-four species: Agava americana, Amarantus gangeticus, *Amygdalus persica*, Areca catechu, *Avena orientalis, Avena sativa, Cajanus indicus, *Cicer arietinum*, Citrus decumana, Cucurbita mischota, Dioscorea japonica, Ervum Ervilia, *Ervum lens*, Fagopyrum emarginatum, Gossypium barbadense, Holcus saccharatus, *Holcus sorghum*, Indigofera tinctoria, Lepidum sativum, Maranta arundinacea, Nicotiana rustica, *Panicum miliaceum*, Raphanus sativus, Spergula arvensis.

7. Subspontaneous like the preceding, but different enough from cultivated varieties to lead the majority of authors to regard them as distinct species. Three species: *Allium ascalonicum (variety of *A. cepa ?*), Allium scorodoprasum (variety of A. sativum ?), Secale cereale (variety of one of the perennial species of Secale ?).

8. Not discovered in a wild state, nor even half-wild, derived perhaps from cultivated species at the beginning of agriculture, but too different not to be commonly regarded as distinct species. Three species: *Hordeum hexastichon* (derived from *H. distichon?*), *Hordeum vulgare* (derived from *H. distichon?*), *Triticum spelta* (derived from *T. vulgare?*).

9. Not discovered in a wild state, nor even half-wild, but originating in countries which are not completely explored, and belonging perhaps to little known wild species of these countries. Six species: Arachis hypogea, Carophyllus aromaticus, *Convolvulus batatas*, Dolichos lubia, Manihot utilissima, *Phaseolus vulgaris*.

10. Not found in a wild state, nor even half-wild, but originating in countries which are not sufficiently explored, or in similar countries, which can not be defined, more different than the latter from known wild species. Eighteen species: Amorphophallus konjak, Arracacha esculenta, Brassica chinénsis, Capsicum annuum, Chenopodium quinoa,[a] Citrus nobilis, Cucurbita ficifolia. Dioscorea alata, Dioscorea Batatas, Dioscorea sativa, Eleusine coracana, Lucuma mammosa, Nephelium Litchi, Pisum sativum, Saccharum officinarum, Sechium edule, Triconsanthes anguina, *Zea mays.*

Total, 247 species.

These figures show that there are 193 species known to be wild, 27 doubtful, as half-wild, and 27 not found wild.

I believe that these last will be found some time or other, if not under one of the cultivated forms, at least in an allied form called species or variety, according to the author. To attain this result, tropical countries will have to be more thoroughly explored, collectors must be more attentive to localities, and more floras must be published of countries now little known, and good monographs of certain genera based upon the characters which vary least in cultivation.

A few species, having their origin in countries fairly well explored, and which it is impossible to confound with others, because each is unique in its genus, have not been found wild, or only once, which leads us to suppose that they are extinct in nature or rapidly becoming so. I allude to maize and the bean. (See pp. 316 and 387.) I mention also, in Article IV, other plants which appear to be becoming extinct in the last few thousand years. These last belong to genera which contain many species, which renders the hypothesis less probable;[b] but on the other hand, they are rarely seen at a distance from cultivated ground, and they hardly ever become naturalized, that is, wild, which shows a certain feebleness or a tendency to become the prey of animals and parasites.

The 67 species cultivated for less than two thousand years (C, F) are all found wild, except the species marked with an asterisk, which have not been found or which are subject to doubts. This is a proportion of 83 per cent.

What is more remarkable is that the great majority of species cultivated for more than four thousand years (A), or in America for three thousand or four thousand years (D), still exist wild in a form identical with some one of the cultivated varieties. Their number is 31 out of 49, or 63 per cent. In categories 9 and 10 there are only 2 of these species of very ancient cultivation, or 4 per cent, and these are 2 species which probably exist no longer as wild plants.

I believe, a priori, that a great number of the species cultivated for more than four thousand years would have altered from their original condition to such a degree that they could no longer be recognized among wild plants. It appears, on the contrary, that the forms anterior to cultivation have commonly remained side by side with those which cultivators employed and propagated from century to century. This may be explained in two ways: (1) The period of four thousand years is short compared to the duration of most of the specific forms in phanerogamous plants. (2) The cultivated species receive, outside of cultivated ground, continual reenforcements from the seeds which man, birds, and different natural agents disperse and transport in a thousand ways. Naturalization produced in this manner often confounds the wild plants with the cultivated ones, and the more easily that they fertilize each other since they belong to the same species. This fact is clearly demonstrated in the case of a plant of the Old World cultivated in America, in gardens, and which later becomes naturalized on a large scale in the open country or the woods, like the cardoon at Buenos Aires, and the oranges in several American countries. Cultivation widens areas, and supplements the deficits which the natural reproduction of the species may present. There are, however, a few exceptions, which are worth mentioning in a separate article.

---

[a] Since this list was printed I have been informed that the quinoa is wild in Chili. Some of the figures need modification in consequence of this error.

[b] For reasons which I can not here express, monotypical genera are for the most part in process of extinction.

CULTIVATED PLANTS WHICH ARE EXTINCT OR BECOMING EXTINCT IN A WILD STATE.

These species to which I allude present three remarkable characters:

1. They have not been found wild, or only once or twice, and often doubtfully, although the regions whence they come have been visited by several botanists.
2. They have not the faculty of sowing themselves, and propagating indefinitely outside cultivated ground; in other terms, in such cases they do not pass out of the condition of adventitious plants.
3. It can not be supposed that they are derived within historic times from certain allied species.

These three characters are found united in the following species: Bean (*Faba vulgaris*), chick-pea (*Cicer arietinum*), ervilla (*Ervum ervilia*), lentil (*Ervum lens*), tobacco (*Nicotiana tabacum*), wheat (*Triticum vulgare*), *maize* (*Zea mays*). The sweet potato (*Convolvulus batatas*) should be added if the kindred species were better known to be distinct, and the carthamine (*Carthamus tinctorius*) if the interior of Arabia had been explored and we had not found a mention of the plant in an Arabian author.

All these species, and probably others of little-known countries or genera, appear to be extinct or on their way to become so. Supposing they ceased to be cultivated, they would disappear, whereas the majority of cultivated plants have become somewhere naturalized and would persist in a wild state.

The seven species mentioned just now, excepting tobacco, have seeds full of fecula, which are the food of birds, rodents, and different insects, and have not the power of passing entire through their alimentary canal. This is probably the sole or principal cause of their inferiority in the struggle for existence.

Thus my researches into cultivated plants show that certain species are extinct or becoming extinct since the historical epoch, and that not in small islands but on vast continents without any great modifications of climate. This is an important result for the history of all organic beings in all epochs.

CONCLUDING REMARKS.

1. Cultivated plants do not belong to any particular category, for they belong to 51 different families. They are, however, all phanerogamous except the mushroom (*Agaricus campestris*).

2. The characters which have most varied in cultivation are, beginning with the most variable: (*a*) The size, form, and color of the fleshy parts, whatever organ they belong to (root, bulb, tubercle, fruit, or seed) and the abundance of fecula, sugar, and other substances which are contained in these parts; (*b*) the number of seeds, which is often in inverse ratio to the development of the fleshy parts of the plant; (*c*) the form, size, or pubescence of the floral organs which persist around the fruits or seeds; (*d*) the rapidity of the phenomena of vegetation, whence often results the quality of ligneous of herbaceous plants, and of perennial, biennial, or annual.

The stems, leaves, and flowers vary little in plants cultivated for those organs. The last formations of each yearly or biennial growth vary most; in other terms, the results of vegetation vary more than the organs which cause vegetation.

3. I have not observed the slightest indication of an adaptation to cold. When the cultivation of a species advances toward the north (maize, flax, tobacco, etc.) it is explained by the production of early varieties, which can ripen before the cold season, or by the custom of cultivating in the north in summer the species which in the south are sown in winter. The study of the northern limits of wild species had formerly led me to the same conclusion, for they have not changed within historic times, although the seeds are carried frequently and continually to the north of each limit. Periods of more than four or five thousand years or changements of form and duration are needed apparently to produce a modification in a plant which will allow it to support a greater degree of cold.

4. The classification of varieties made by agriculturists and gardeners is generally based on those characters which vary most (form, size, colors, taste of the fleshy parts, beard in the ears of corn, etc.). Botanists are mistaken when they follow this example; they should consult those more fixed characters of the organs for the sake of which the species are not cultivated.

5. A noncultivated species being a group of more or less similar forms, among which subordinate groups may often be distinguished (races, varieties, subvarieties), it may have happened that two or more of these slightly differing forms may have been introduced into cultivation. This must have been the case especially when the habitation of a species is extensive, and yet more when it is disjunctive. The first case is probably that of the cabbage (*Brassica*), of flax, bird cherry (*Prunus avium*), the common pear, etc. The second is probably that of the gourd, the melon, and trefoil haricot, which existed previous to cultivation both in India and Africa.

6. No distinctive character is known between a naturalized plant which arose several generations back from a cultivated plant and a wild plant sprung from plants which have always been wild. In any case, in the transition from cultivated plant to wild plant the particular features which are propagated by grafting are not preserved by seedlings. For instance, the olive tree which has become wild is the *oleaster*, the pear bears smaller fruits, the Spanish chestnut yields a

common fruit. For the rest, the forms naturalized from cultivated species have not yet been sufficiently observed from generation to generation. M. Sagot has done this for the vine. It would be interesting to compare in the same manner with their cultivated forms Citrus, Persica, and the cardoon, naturalized in America, far from their original home, as also the Agave and the prickly pear, wild in America, with their naturalized varieties in the Old World. We should know exactly what persists after a temporary state of cultivation.

7. A species may have had, previous to cultivation, a restricted habitation, and subsequently occupy an immense area as a cultivated and sometimes a naturalized plant.

8. In the history of cultivated plants I have noticed no trace of communication between the peoples of the Old and New worlds before the discovery of America by Columbus. The Scandinavians, who had pushed their excursions as far as the north of the United States, and the Basques of the Middle Ages, who followed whales perhaps as far as America, do not seem to have transported a single cultivated species. Neither has the Gulf Stream produced any effect. Between America and Asia two transports of useful plants perhaps took place, the one by man (the Batata, or sweet potato), the other by the agency of man or of the sea (the cocoanut palm).

THE PRINCIPAL DROUGHTS IN THE PERIOD FROM 1870 TO 1906 AND THEIR INFLUENCE ON THE CORN CROP.

By A. F. Woods,
Assisted by E. H. Bradley,
Bureau of Plant Industry, U. S. Department of Agriculture.

Prof. A. J. Henry, in the Yearbook of the Department of Agriculture for 1907, stated:

> The years of minimum rainfall or drought from 1871 to 1896 fall in groups separated by irregular intervals. The first group centers about 1871; the second, 1881; the third, 1887; and the last, 1894–95. The drought of 1887 was severe in some months, but not consistently so throughout the entire season. The droughts of 1881 and 1894 were widespread and severe. The former was confined principally to States east of the Alleghenies, while the latter was felt from Nebraska eastward to Massachusetts and southward to Alabama.
>
> Prior to 1870 the few records available indicate a severe drought in 1860 in Kansas and western Missouri, more severe than has since been experienced. Widespread drought in the central valleys and Lake region also occurred in 1863. The periods of extensive drought in chronological order are, therefore, 1860, 1863, 1870–71, 1881, 1887, and 1894–95.[a]
>
> There have been, of course, several local droughts in various portions of the United States during the intervening years, as there must always be in a territory of such vast extent.
>
> The smallest amount (of rainfall) that may be expected in the great corn and wheat regions of the central valleys does not vary greatly from 9 to 10 inches (from April 1 to September 30). In the South Atlantic and Gulf States the fall in the year of least rain ranges from a maximum of 20 inches in central and northern Florida to less than 15 inches in the Mississippi Valley and a considerable fringe of country to the westward. The amount of rain that falls in the year of severe drought in the greater part of the Southeastern States is sufficient for the growth and maturity of staple crops if properly distributed. Success in agricultural pursuits, so far as conditioned upon the rainfall, should therefore be more easily achieved in the Southeastern States than elsewhere, particularly in regions of precarious rainfall.[b]

In Bulletin Q of the Weather Bureau, Climatology of the United States, by Henry, published in 1906, attention is called especially to the severe droughts of 1870, 1874, 1881, 1886, 1887, 1893, 1894, and 1895. The following pages contain extracts from Bulletin Q and data obtained from articles on weather and crop conditions, published annually in the Yearbooks of the Department of Agriculture.

DROUGHT OF 1870.

Local in character; southern Ohio, Wisconsin, and Missouri.

In southern Ohio the rainfall from August 1 to September 30 was about 1½ inches.

---

[a] In addition to the drought years mentioned above, a severe drought occurred in 1901, which cut the corn crop very short. This drought prevailed from June 24 to July 29—thirty-six days—over the States of the central valleys and middle Rocky Mountain region, and also in lesser degree in the Lake region, the Ohio Valley, and Tennessee. A very serious drought also prevailed during 1890 over the greater portion of the corn belt.

[b] A. J. Henry, Rainfall of the Crop Season, Yearbook, U. S. Dept. Agr., 1897.

At Milwaukee the precipitation for April was ½ inch; May, 6/10 inch; June, 2½ inches.

Dry weather also prevailed in Missouri.

The drought apparently had no effect on corn; in fact, the average crops were greater for 1870 than for preceding year, being 6 bushels above the average for forty years in Ohio, 7 above Wisconsin, but 3 below the average in Missouri.

DROUGHT OF 1874.

A severe drought prevailed in Kansas, Nebraska, Iowa, Missouri, Illinois, and Indiana, and in less marked degree in the middle and lower Mississippi valleys.

Eastern Kansas was affected the worst, where for a period of eighty days slightly over 2 inches of rain fell. At Leavenworth, Kans., from June 15 to July 8—twenty-four days—practically no rain fell.

Average yield of corn in bushels per acre.

State.	1873.	1874.	1875.	Normal.
Indiana	25.6	27.0	34.0	31.4
Illinois	21.0	18.0	34.3	30.3
Iowa	29.0	29.2	35.0	32.4
Missouri	23.5	16.0	36.6	29.5
Nebraska	35.0	10.0	40.0	30.4
Kansas	39.1	10.5	40.0	27.3
Kentucky	29.5	25.0	33.3	26.4
Tennessee	22.5	16.8	26.5	22.1
Mississippi	15.5	13.8	18.0	15.0
Louisiana	16.5	15.5	15.5	16.8
Arkansas	23.5	12.6	30.0	21.0

NOTE.—This drought prevailed in 11 States, 8 of which showed reduced production of corn as compared with the previous year (1873), and all showed lower yields than those of the following year (1875). The yields in all these States were also below the normal for the forty years, being 4 below in Indiana, 12 below in Illinois, 3 in Iowa, 14 in Missouri, 20 in Nebraska, 17 in Kansas, 1½ in Kentucky, 5 in Tennessee, 1 in Mississippi, 1 in Louisiana, and 8 in Arkansas.

DROUGHT OF 1876.

A severe drought occurred this year in New England, the Middle Atlantic States, the Ohio Valley, and lower Lake region; it also prevailed quite generally south of the Ohio River and east of the Mississippi. No figures as to precipitation are available.

Only in the following States of the affected region, however, did the corn yield fall below the normal for the forty-year period, 1867-1906:

Average yield of corn in bushels per acre.

State.	1875.	1876.	1877.	Normal.
Maine	30.5	31.0	36.0	33.2

every State east of the Mississippi River, with the exception aine, New Hampshire, and Vermont, the yield was lower than e preceding year, 1880, and in nearly every case lower also for the yields for the following year, 1882. This was true also yield as compared with the average for the forty-year period. production of corn in California, Oregon, and Nevada was elow the forty-year average for this year. For the whole coun- e average yield was 18.6 bushels, as compared with 25.5 bushels e forty years—the lowest annual average for the forty-year l, with the exception of the year 1901.

DROUGHTS OF 1886 AND 1887.

6.—Severe drought in Kansas, Nebraska, the Dakotas, Iowa, esota, and western Wisconsin.

7.—This year was also characterized by a severe and prolonged ht over the Ohio Valley, Michigan, Indiana, Illinois, Missouri, Iowa, Nebraska, Kansas, Minnesota, Louisiana, Mississippi, Alabama, and portions of the Middle Atlantic States.

At Iowa City, Iowa, from May 13 to the end of July, 1886, a period of 83 days, 0.95 inch of rain fell, being scarcely 1 per cent of the normal.

"The drought of 1887 was severe in some months, but not consistently so throughout the entire season." (A. J. Henry, in Yearbook, 1897.)

[a] 1887. [b] 1886.

The area of the drought of 1886 probably also extended over the eastern part of the country, although data are lacking on this point. An examination of the foregoing figures, however, shows marked reductions in yield for this year in New Jersey, Pennsylvania, Delaware, Maryland, and Virginia, doubtless due to drought.

The drought of 1887 appears, from a study of the figures, to have been particularly severe in the Ohio Valley and Lake region, and in the central Mississippi and Missouri valleys, where reductions in yield from the normal of from 6 to 13 bushels per acre were noted.

DROUGHT OF 1890.

Beginning with July, a drought of considerable proportions began over the greater part of the States embraced within the corn belt, the amount of precipitation for the month ranging, at many points, from 50 to less than 25 per cent of the average fall. Reports from numerous correspondents over the above-mentioned section indicate that corn was suffering seriously from the prevailing dry weather. The deficiency in rainfall continued during August and into September over a large portion of the more northern and western States of the corn belt.

le the above figures call attention to the principal States af- by the drought of 1890, with the exception of most of the England States and South Carolina, every State in the Union d reduced yields of corn as compared with the average for the year period, and the average for the whole country fell 5 bushels the normal for the period.

DROUGHTS OF 1894 AND 1895.

fessor Henry, in Climatology of the United States, says:

> greatest drought this country has experienced in the past 100 years, to its intensity and the extent of territory covered, culminated in the Mississippi and Missouri valleys in 1894, and in the Lake region and coast districts in 1895.

DEFICIENT RAINFALL IN 1893.

drought of 1894 was the culmination of a period of deficient rainfall h temperatures that began during the early summer of 1893.

DROUGHT OF 1894.

seasonal rainfall from March 1 to October 1 was largely deficient from ssouri Valley eastward to the Atlantic, including the coast States from rolinas northward. A marked deficiency also occurred in the Central tates and California. The seasonal deficiency in rainfall exceeded 10 in portions of New England and the Middle Atlantic States, eastern , on the central Gulf coast, eastern Tennessee, and from the Ohio Valley ard over the central Mississippi and Missouri valleys. In but one week, pril 30 to September 10, did the rainfall for Huron, S. Dak., which is in ion of severe drought, exceed the weekly average at that station, while nperature was above the normal throughout almost the whole of the eriod. While the actual deficiency in rainfall of 12 inches in central Iowa qualed or exceeded in portions of Florida and eastern Tennessee, in r section of the country east of the Rocky Mountains did the seasonal l form so small a percentage of the normal amount as in Iowa and the eastern portions of Nebraska and South Dakota, where the actual rainfall was only about 50 per cent of the usual seasonal amount, although portions of New England, the Middle Atlantic States, and eastern Tennessee received less than 60 per cent of the seasonal rainfall.

The extensive and protracted drought of July and August was very injurious to crops, most seriously affecting the corn crop, the principal corn-producing States being covered by the region of severest drought.

Rains of April were general deficient in almost all parts of the country, except northern Pacific coast, upper Missouri Valley, and upper Mississippi Valley, although the deficiency east of the Mississippi was not especially marked except along the south Atlantic coast.

In May the greatest deficiency in precipitation, 3 inches or more, occurred in the States of South Dakota, Nebraska, Kansas, Iowa, Illinois, and Missouri.

In June, July, and August the drought continued unabated in these States and extended into the upper Missouri and Ohio valleys, the Lake region, and portions of New England and Middle Atlantic States. The months of July and August were exceptionally dry in the Ohio Valley, Lake region, Missouri Valley, and middle and upper portions of the Mississippi Valley. Over this great area less than 2 inches of rain, on the average, fell in two months. In Iowa the average precipitation for July was 0.6 inch—3.7 inches below the normal; in August, 1.6 inches—2 inches below normal. The rainfall of September was not far from normal in the drought-stricken region of the Middle West, but continued below normal in a number of other districts.

DROUGHT OF 1895.

The shortage of rainfall during 1895 was almost as great and as widespread as in the previous year, but the region of greatest intensity was shifted from the middle Mississippi Valley eastward to the Lake region and upper Ohio Valley.[a]

EFFECT OF DROUGHT ON CROP PRODUCTION.

Notwithstanding the widespread deficiency in annual precipitation, the total crop production in the United States for both 1894 and 1895 did not fall greatly below a normal year, except that the corn crop for 1894 and the hay crop for 1895 were both short crops. The average yield per acre for corn in 1894 was 19.4 bushels, as against an average of 23.5 bushels for ten years, 1892-1901.

The corn yield for 1894 was generally below the normal, and was much below it in Kansas, Iowa, and Nebraska—in the two last the lowest recorded for those States. In both States the precipitation for the summer was also the least recorded, while in July the average rainfall for Iowa and eastern Kansas and Nebraska was only about one-half inch. In Iowa, the month of July, 1894, was the driest ever experienced.

According to Mr. J. Warren Smith,[b] of the United States Weather Bureau, the precipitation for 1895 in the great corn States of the Middle West was abundant, and excessive in Missouri and Kansas. An examination of the available statistics fails to show any marked decline in corn yields in 1895; in fact, the general average for the whole country was above the normal.

---

[a] See Climatology of the United States, by A. J. Henry, p. 52. Statistics show, however, that, even in the Lake region and Ohio Valley, the yields were lower for 1894 than for 1895; in fact, the general average for the whole country in 1895 is above the normal.

[b] See Relation of Precipitation to Yield of Corn, by J. Warren Smith, Yearbook, Dept. of Agr., 1903.

[a] The drought of 1894 was the culmination of a period of deficient rainfall and high temperatures that began during the early summer of 1893.

WEATHER CONDITIONS FOR 1896 AND 1897.

The corn crop of 1896 was above the average for the country for the 40-year period. Available data show that for the greater part of the corn belt abundant rains prevailed, with the exception that in the Western Gulf States the precipitation for the whole year was 12.5 inches below the normal rainfall, and in the South Atlantic States it was 10.7 inches below.[a]

In 1897 droughty conditions prevailed over portions of Texas, Arkansas, Missouri, Tennessee, Kansas, Louisiana, Virginia, Kentucky, and North Carolina. Cool weather and frosts during the early summer seriously injured corn in Wisconsin, Minnesota, and North Dakota.

---

[a] See Rainfall of the Crop Season, by A. J. Henry, Yearbook, Dept. of Agr., 1897, p. 616.

Average yield of corn in bushels per acre.

State.	1896.	1897.	Normal.

Wisconsin	37.0	32.0	31.2
Minnesota	30.5	26.0	30.0
North Dakota	35.0	17.0	22.1

WEATHER CONDITIONS FOR 1898.

On the whole the season was generally favorable for corn.

Severe local droughts occurred in California from about April 1 to May 15 (interrupted with slight rainfall in the southern portion during the week ending May 2). Excessive heat and drought occurred during the latter half of August in parts of Nebraska, Kansas, Missouri, and generally in the States of the eastern Rocky Mountain slope.

LOCAL DROUGHT OF 1899.

Season generally very favorable for corn. Late corn was injured considerably by drought, which prevailed from about August 10 for two weeks in parts of Missouri, Kansas, and Nebraska, and from about August 20 for three to four weeks over the greater part of Oklahoma, Texas, southern Missouri, and States of the central Mississippi and Ohio valleys.

A glance at the following figures will show the effect of the drought:

Average yield of corn in bushels per acre.

State.	1899.	Normal.	State.	1899.	Normal
Kentucky	21.0	26.4	Missouri	26.0	28.5
Tennessee	20.0	22.1	Kansas	27.0	27.2
Arkansas	20.0	21.0	Nebraska	28.0	30.4
Oklahoma	19.0	23.5	Michigan	25.0	30.8
Texas	18.0	20.0	Iowa	31.0	32.4

LOCAL DROUGHT OF 1900.

The Weather Bureau reports the year for the country as a whole as a good corn year.

A condition of drought occurred from about May 7 to July 1, with intermittent periods of very slight rainfall, in portions of the upper Missouri Valley. The droughty conditions were reported to be especially severe in eastern Montana and North Dakota, and the following figures, so far as corn crop is concerned, show the influence of the dry weather in these States:

Average yield of corn in bushels per acre.

State.	1900.	Normal.
North Dakota	16.0	22.6
Montana	15.0	25.0

DROUGHT OF 1901.

A severe drought occurred in 1901, which cut the corn crop very short.

This drought prevailed from June 24 to July 29—thirty-six days—over the States of the central valleys and middle Rocky Mountain region, and also in lesser degree in the Lake region, the Ohio Valley, and Tennessee.

After July 29 rains occurred over the larger part of the drought area of the Mississippi and upper Missouri valleys, but drought continued about a week longer, becoming very serious in the Ohio Valley and Tennessee.

Average yield of corn in bushels per acre.

Indian Territory		12.0	24.9	27.2

The average yield for the whole country this year was only 16.7 bushels per acre, which is the lowest average yield reported for the United States since 1867.

WEATHER CONDITIONS FOR 1902.

A drought of several weeks' duration prevailed over the Gulf States during June and July. A severe drought also occurred over the central and southern Rocky Mountain districts from July 25 to September 20.

The season was characterized, however, in the greater portion of the corn belt by excessive rains and unusually cold weather, especially over the central and northern portions of the belt and in the New England States. Cold weather also prevailed in the northern and central Rocky Mountain regions. Killing frosts occurred in New England and in the Lake regions in June; late corn was seriously damaged by heavy frosts over the northern part of the corn belt, especially west of the Mississippi River, frost with ice occurring as early as August 29 in exposed places in the northern Rocky Mountain region.

While the yield for the entire country was slightly above the normal, it may be seen from the following figures that the cold weather was responsible for very reduced yields of corn in a number of States. In the Gulf States, however, i. e., Alabama, Mississippi, Louisiana, and Texas, the low yields were undoubtedly due to drought.

Average yield of corn in bushels per acre.

State.	1902.	Normal.

Mississippi	11.5	15.0
Louisiana	12.5	16.8
Texas	8.1	20.0

WEATHER CONDITIONS FOR 1903.

May 4.—This week was unseasonably cool over much the greater part of the country, the minimum temperatures on April 30 and May 1 and 2 being the lowest recorded in the last thirty years at nearly all Weather Bureau stations from the central and west Gulf coasts to the upper Missouri Valley, and also at a number of stations in the central Mississippi and Ohio valleys, Lake region, and New England. Unseasonably low temperatures checked the growth of all vegetation, and heavy frosts and freezes caused much damage. * * * The early planted corn was extensively killed by the freeze during the latter part of the week in Missouri, Kansas, Oklahoma, and Texas, and the crop suffered from cold weather throughout the Southern States.

After the early freeze corn was generally replanted in the Southern States and Gulf States, and the remainder of the season was generally favorable for corn in these sections, where average crops were obtained. Replanting was also necessary in many other sections where early corn had been planted.

The whole crop season was abnormally cool over the Missouri and upper Mississippi valleys, and much corn was seriously damaged by excessive rains.

Drought occurred from May 15 to about June 15 in the northern portion of the Middle Atlantic States and in the New England States. The droughty conditions in the Middle Atlantic States were reported to be especially severe in eastern New York.

Average yield of corn in bushels per acre.

State.	1902.	1903.	1904.	Normal.
Maine	21.7	30.2	39.7	33.2

Nebraska	32.3	26.0	32.8	30.4
Kansas	29.9	25.6	20.9	27.2

WEATHER CONDITIONS FOR 1904.

The season was generally cool and rainy over the greater part of the corn belt.

A three-weeks' drought prevailed during May over the east Gulf States, but was not serious enough to cause any reduction in the yield of corn, good average crops being secured in these States.

The cool weather, rains, lack of sunshine, and lack of cultivation were probably responsible for a decline in yield in several of the States.

Average yield of corn in bushels per acre.

State.	1903.	1904.	1905.	Normal.
New York	25.0	27.3	31.5	31.0
Michigan	33.5	28.6	34.0	30.8
Minnesota	28.3	26.9	32.5	30.0
Missouri	32.4	26.2	33.8	28.5
North Dakota	25.2	21.2	27.5	22.1
Kansas	25.6	20.9	27.7	27.2
Montana	24.1	22.2	19.4	24.3

WEATHER CONDITIONS FOR 1905.

The season in general was very favorable for corn.

Planting was delayed by cold weather and rain, which continued as late as June 1 and was general throughout the corn belt. Germination was slow and corn suffered from lack of cultivation.

Some damage was done to corn as a result of rains and high winds in the lower Missouri Valley, especially in Kansas and Missouri. In Missouri corn was extensively blown down, but the yield was heavy notwithstanding this. Wind also did considerable injury in Nebraska, Arkansas, and Ohio.

No serious droughts.

The yield was about average in all States except Montana, Oregon, Louisiana, and Arkansas; in many States considerably above the average.

WEATHER CONDITIONS FOR 1906.

The conditions over the country were generally favorable for corn, but local droughts prevailed over portions of the West Gulf States, the lower Mississippi Valley, and portions of Missouri and Tennessee during the week ending May 14 and for two weeks in June.

With the exception of Montana, however, every State in the Union yielded crops above the normal for the forty-year period, the average for the whole country being higher than for any year since 1872.

STATISTICS OF CORN.

Average yield of corn in the United States, in bushels per acre, for the forty years 1867–1906.

(Marked decreases in yield, as compared with the average for the forty-year period, are indicated by italic and boldface figures. Italic figures show decreased yields due principally to severe local or sectional droughts. Boldface figures show the low yields due to the great general droughts.)

The principal drought years covered by the above table, where the condition of minimum rainfall was more or less general throughout the United States, were 1874, 1881, 1887, 1890, 1894, and 1901.

1883.—Notable decreased yields in New York, the South Atlantic States, Ohio Valley, Lake region, Minnesota, and Iowa.

1886.—Severe drought in Kansas, Nebraska, the Dakotas, Iowa, Minnesota, and western Wisconsin.

1890.—Decreased yields in Ohio and Indiana, Iowa, Nebraska, Kansas, Kentucky, Tennessee, Alabama, Arkansas, and Texas, due to a drought of unusual severity in the great corn States; other less notable reductions in yield in other States.

1893.—Decreased yields noted particularly in Rhode Island, New Jersey, Pennsylvania, South Carolina, Ohio, Indiana, Michigan, Kansas, Arkansas, Colorado, and Wyoming. ("The drought of 1894 was the culmination of a period of deficient rainfall and high temperature that began during the early summer of 1893."—A. J. Henry.)

1902.—During June corn suffered from drought in the central and west Gulf States. (Early corn was injured by frost in the Ohio Valley and Lake region, and late corn was seriously damaged by heavy frosts over the northern portion of the corn belt, more especially to the westward of the Mississippi River.)

1903.—Drought prevailed in the northern portion of the Middle Atlantic and the New England States from May 15 to about the middle of June.

CROP PRODUCTION ALONE NOT A MEASURE OF THE CONDITION OF AGRICULTURE.

By WALTER T. SWINGLE,

Bureau of Plant Industry, United States Department of Agriculture.

The question as to whether crop production per acre is increasing or decreasing is of so general a nature as to have little direct relation to the condition or needs of the agriculture of the country as a whole. A large number of factors will always be found working toward increased production, and a large number toward diminished production. In one region the balance will swing one way; in another region the other way. The general average for the whole country is merely an arithmetical mean and becomes of interest only when a detailed analysis of the facts reveals some general efficient cause for the observed advance or decline.

Agriculture in this country is now passing through a period of rapid changes. In many ways its condition may be compared with that of electrical engineering a quarter of a century ago, when discoveries succeeded each other so rapidly that expensive machinery and equipment were often relegated to the junk heap before the varnish had been dimmed.

The constantly extending applications of science to agriculture are working revolutions in farm practices; great changes are taking place in the crops grown, the methods of culture, and in the handling and disposal of the crop itself. These applications of science to farming, which have assumed importance only during the last twenty-five years, make for increased production and for increased certainty of production.

The demonstration that the leguminous crops enrich the soil in which they grow with nitrogen abstracted from the inexhaustible atmospheric supply has, at a single stroke, solved the problem of a cheap and convenient supply of the most important and most expensive element of plant food and the very one whose exhaustion was greatly feared by leading men of science scarcely a decade ago. The proper utilization of leguminous plants in crop rotations becomes, in the light of this discovery, of absolutely fundamental importance in agriculture. Already production has been greatly increased in many sections of this country through the skillful use of alfalfa, clover, vetches, cowpeas, and others of the beneficent crops of the pulse family.

At the same time, thanks largely to the researches of the investigators connected with state experiment stations, much has been taught the farmer as to the needs of various crops and soils in other elements of plant food besides nitrogen. At the same time the state fertilizer controls have rendered fraud and excessive charges almost impossible. No one familiar with American agriculture, especially in the Eastern States, can deny that vastly increased production has resulted from this work of the state experiment stations in preventing fraud in the sale of artificial fertilizers and in showing how fertilizers can be used to the best advantage.

During the past three decades great progress has been made in recognizing, curing, and preventing plant diseases, the most insidious of the farmer's enemies. Tens of millions are saved annually to the country by the use of up-to-date methods of fighting insect and fungous enemies. In many cases both the pests themselves and the possibility of preventing their injuries were alike unknown two decades ago. Vastly increased production and, what is even more important, increased certainty of production have resulted from this brilliant new arm forged by science for man's protection.

Plant breeding—a branch of applied science having even greater possibilities for aiding the progress of agriculture than plant pathology—is of still more recent birth. General interest in the methods and aims of plant breeding dates back scarcely a decade and, as would be expected, only a tithe of what will be done has as yet been accomplished. Nevertheless, great increases in yield, in uniformity of product, in hardiness, in drought and disease resistance, and in other useful qualities of our principal crop plants have already resulted from the tireless activities of a handful of enthusiastic disciples of the new branch of applied science.

The organized work in the introduction of new and superior varieties of crop plants from all parts of the world is even younger than plant breeding, yet already half a dozen new crops, yielding products whose annual value reaches into tens of millions, testify to the striking utility of this line of work.

The scientific study of the soil and of climatic and cultural needs of the varieties of our principal crop plants has only just begun, but is sure to become of the greatest importance in growing crops with the maximum of efficiency—utilizing plants to the utmost through an intimate knowledge of their strong and weak points—in other words, growing crops by brains. In preventing "booms" that ruin thousands through false ideas as to the needs and limitations of crop plants, great good will be accomplished by life-history investigations. Much progress has been made already in the working out of the merits and demerits of the numerous new varieties of cotton, corn, alfalfa, date palms, and other staple crops that have been placed at the disposal of the experimenter during the past decade through the activities of the plant introducers and plant breeders.

As plant breeding and plant introduction advance, the need becomes more acute for a critical analysis and study of all varieties of crop plants, with a view to growing them in the localities and in the manner they require to secure the maximum yield. These three new branches of agricultural science—plant breeding, plant introduction, and plant life-history investigations—will, developing hand in hand, revolutionize all branches of crop production and ultimately greatly increase the yield per acre and decrease the risk of failure.

Recent investigations in the methods of picking, packing, and shipping perishable crops, especially fruits and vegetables, have decreased the cost and increased the amount of the net yield per acre of these crops. All branches of agriculture have been stimulated by the great advances in transportation facilities, by the extension of the rural free delivery, the discovery and extension of the telephone, the invention of the milk separator, improved farm machinery, and other mechanical aids for the farmer.

In the light of these numerous applications of science to agriculture, most of them of very recent date and most of them potent for good, it would seem an idle question to ask whether crop production is now increasing or diminishing.

As a matter of fact, however, there is a reverse side to the picture, and many powerful factors are at work tending to lessen production.

First of all, there has been a slow but general decline in the fertility of farm lands since the forests were cleared and the prairies broken. Wasteful methods of husbandry have contributed and erosion has been insidiously at work until in some regions the decline in productiveness has become alarming.

This decline of fertility in the older parts of the country has been both emphasized and aggravated by the bringing into culture, during the last forty years, of enormous areas of exuberantly fertile new lands of the Great Plains, which through improved methods of transportation have been enabled to compete successfully with regions thousands of miles away. This sharp competition of virgin soils in the West has in many cases prevented in the East the profitable use of commercial fertilizer in growing the accustomed staple crops, and has forced a complete change of farm practices, often ending in cultivated fields being turned into permanent pastures or wood lots.

Agricultural labor has become poorer, scarcer, and much dearer during the last few decades. The immigration, largely of the country peasantry of northern and western Europe, formerly so abundant as to furnish a steady supply of the best kind of farm labor, has in recent years almost ceased, and the hordes of immigrants now flocking to our shores from eastern and southern Europe are largely from the cities and even when they are peasants are so unfamiliar with our methods of agriculture as to be of little worth as farm hands. As a matter of fact, few seek employment in the country when they reach the New World.

The growth of the great industrial centers has also acted to draw laborers from the country to the mines and mills where wages were higher and where the eight-hour day is possible, the latter something almost impossible for the farmer to grant. There can be no doubt that the increasing scarcity of good farm labor has in many regions led to a considerable decline in production.

The present industrial tendency to form gigantic trusts that control the marketing of commodities, with little regard for supply and demand, has been brought sharply home to the farmer by the success of the beef trust in stifling competition and manipulating the transportation and sale of live stock to its own advantage. Improved methods of farm practice tend to turn as many crops as possible into the more easily transportable form of cattle, hogs, sheep, and other live stock, and the success of the beef trust in controlling prices to the disadvantage of the farmer has greatly impeded the spread of better methods of farming and in many cases led to a direct decline of production.

Finally the most important cause of decline in production and decay in the intellectual tone of many of the older farming communities is the draining off of almost all the brighter minds to the large cities. The wide ramifications of the modern railway, telegraph, express, and other large business enterprises, have enabled them to take on as apprentice the bright country boy at the small station and gradually promote him as he develops, each step away from the country and toward the great city.

Even the state agricultural colleges and universities of some of the great agricultural States have acted practically as great employment agencies run at state expense to get farmers' boys and girls paying positions off the farm.

The bright country boy, tired of the endless chores of the farm, finds that he can be educated to be an electrical engineer, a civil engineer, a printer, an architect, a machine-shop foreman, or in any one of a dozen other professions that appeal to his youthful mind because of the attractiveness and stimulating character of the work and because of the relatively high salaries paid to the best young men shortly after graduating.

The farmer's son is too young (in some institutions he must choose his future career when he is only 15 years old) and too inexperienced to see the drawbacks in such careers—that he usually is a hired man all his life; that his children grow up in the big cities and almost never equal their parents in energy or initiative; that his own health declines, and that cares multiply faster than his salary increases. All this is wrong. Positions in the technical world should be filled largely from the city population that can not under any ordinary circumstances become farmers.

A fair proportion of the brightest minds should be induced to remain on the farm, and to do this every effort should be made to make farm life attractive to the bright boys and girls. It is a great mistake to imagine that mere technical discussion on methods of farm practice, with which the farmer's boy is often more familiar than his instructor, or purely mercenary motives, can hold the boy on the farm. He knows, even if his salaried instructor does not, that the intelligent boy with little or no capital can make much more off the farm than on it—at first.

The remedy lies rather in the study of science, whose recent brilliant applications to agriculture tend to interest the talented youth not only in the direct improvement in crop production, but also in science itself, which he finds to be a fascinating and stimulating mental discipline, at the same time work and recreation, a noble study much broader and much more satisfying than any of the practical applications that may be made to the industries, important and interesting as they are.

Farm life, with its multitudinous contacts with nature, with its intimate relations to the biological and physical sciences, is really the ideal place for the scientific investigator. Already the tendency is being manifested in plant breeding to decentralize and to put on the farm the breeding up of races of the crop plants under the particular environmental surroundings they must endure when grown on a commercial scale. Commercial success has already been attained by plant breeding on the farm. The intellectual interest aroused by the breeding of a new flower, a new berry, or a new and superior strain of corn far exceeds in importance the not inconsiderable money value of such new creations.

Other lines of research can, with great advantage, be moved out to the farm, where research is conducted under the most favorable conditions by persons themselves vitally interested in the problems and thoroughly familiar with the local conditions. In large institutions it is necessary to turn over more and more of the actual work of investigation to assistants, often poorly fitted and but superficially interested in the problem.

Farm research, however, is not merely a remote end devoutly to be hoped for; it exists now, and it is to further it and to work further decentralization of research that private, state, and national effort should be directed. It is true that only a few men are able to undertake the more difficult lines of scientific research, but it is just these few who, living on the farm, will be the leaders of their communities in the improvement of agriculture and the helpers of their neighbors in minor but still vitally important lines of experimentation. It is always the gifted few who are able to look beyond the immediately pressing problems of the day and plan for the future.

To drain the country of its brightest minds in the future as completely as has been done during the past few decades is to invite the complete intellectual decline of the farming class, the entry of rich landowners, and the creation of a servile tenantry, possibly with a resultant increased production per acre, but at what a cost!

To increase the attractiveness of farm life and to add intellectual interest to rural occupations, to encourage with every means at the disposal of the Government the country boy who honestly tries to seek for truth, with the end in view of retaining a fair proportion of the brightest minds on the farm, should be given immediate attention before it is too late. A free, active, and intelligent country population is the backbone of any country, and no increase in wealth, no triumphs in the industries, can permanently offset the loss of the nation's greatest asset.

THE AGRICULTURAL RESOURCES OF THE EASTERN UNITED STATES; THEIR DEVELOPMENT AND CONSERVATION.

By E. C. Chilcott,
Bureau of Plant Industry, U. S. Department of Agriculture.

Within the last few years the idea that the agricultural resources of the United States are being rapidly depleted, and that crop production per acre is rapidly falling off, seems to have met with quite general acceptance. I do not believe that this idea is in accord with either the official statistics furnished by this department and the various state organizations dealing with the subject or with the observations of those who have given the subject the most careful consideration. It is not difficult, however, to see how such an impression might be made upon the mind of the superficial observer, or one who was interested mainly in studying the subject from the viewpoint of the great transportation companies. It is undoubtedly true that there are many farms located in nearly, if not quite, every county of the United States where the production of some one crop has materially decreased within the last decade. It is also probably true that there are many farms where not only one crop, but all of the crops produced have decreased both in aggregate quantity per farm and in yield per acre. But, on the other hand, there is an equal or greater number of farms where an increase both in aggregate production and in yield per acre has been experienced. So that, on the whole, when the entire country is taken into consideration, both the yield per acre and the gross amount produced have been on the increase, not only for the last decade but for the last quarter of a century. It would be manifestly impossible, in an article of this length, to point out the many combinations of causes that have led to the increase or decrease of crops upon farms, either considered individually or grouped by counties or States. I think, however, that a consideration of a few concrete examples that have come under my observation may help to throw light upon the problem.

AGRICULTURAL CONDITIONS IN WESTERN NEW YORK.

Upon paying a visit to a locality in western New York with which I had formerly been very familiar, after an absence of twenty-three years I noted many facts which I believe have a very direct bearing upon the subject under discussion. Among these are the following: I found that many of what had formerly been the richest and most productive farms located within a radius of 12 miles of the city of Buffalo had very materially decreased in agricultural production, although their value, due to their proximity to the city, had considerably increased. An inquiry into the reason for these conditions revealed the fact that in nearly every instance the cause of the decreased production was not due to a decrease in the fertility or productive capacity of the farm, but was on account of the difficulty in obtaining efficient farm laborers at a reasonable price. The cause of this scarcity of farm laborers was generally attributed to the fact that the immense growth of manufactures in the city of Buffalo had served to attract the laborers who were formerly engaged upon farms. These manufacturers paid higher wages than the farmers were able to pay, but, on the other hand, the opportunities for morally and physically healthful surroundings are very much better upon the farm than in those parts of the city occupied by the laborers in the factories. This consideration seems to be generally overlooked by the laboring classes. They consider only the difference in cash wages without any regard to the relative amount of comfort and the welfare of their families in country and in city. I believe that right here is an opportunity for a campaign of education and enlightenment. If the laboring classes in the congested manufacturing centers could be shown the desirability of establishing homes where they could rear and educate their families in a morally and physically healthy environment, where they could have a small piece of land upon which to raise a very considerable portion of the food required by the family, without any expense whatever except the labor of those members of the family not actively engaged as wage-earners, it would seem that there could be found many men, now engaged as laborers in factories, but who had formerly had sufficient experience to enable them to perform the ordinary work on a farm in a satisfactory manner, who would gladly exchange the somewhat higher wages obtainable in the city for the advantages offered by the country.

Another important factor which always has operated and which always will operate to deplete the ranks of farm laborers is the fact that the more progressive among them are constantly becoming themselves landowners. The cheap lands of the West have proved very attractive to this class, and as the western lands have increased in value these people have turned their attention more and more to the relatively cheap but poorer lands of the Eastern States. This movement, of course, should be encouraged rather than discouraged, as many of the very best farmers in this country originally belonged to this class. In fact it may be said that the agricultural development of the Central and Western States is due very largely to men who had formerly been employed as farm laborers, and who by frugality and economy had succeeded in saving enough money to enable them to get a start for themselves where cheap land was obtainable.

The explanation of the seemingly anomalous fact that many of the rich farms of western New York have very considerably increased in value and at the same time have decreased in productivity is probably as follows: Many of these farms have been inherited by their present owners and are looked upon not as investments of so much capital but rather as inheritances that should be retained in the family regardless of the fact that they are not yielding a fair interest on the investment. In other instances, the owners realize that their farms are not profitable investments under existing economic conditions, but they believe that conditions will so change that their farms will eventually prove to be so, and this hope, combined with the sentimental reasons already mentioned, serve to discourage any general tendency to sell this class of farm property. A sufficient amount of real estate transfers is being made in the vicinity of these farms to establish and maintain a market price for land, but in almost every instance the purchasers are either men of wealth from the city, who buy the farms for country homes or as a fad where they may spend the money which they make in other lines of business, or foreigners, mainly Germans, who depend largely upon the members of their own families for supplying the necessary labor for conducting the farms. Very few farmers or successful business men would consider this class of farms a profitable investment where all of the labor must be hired.

Where the changes described in the preceding paragraph have been taking place changes of an entirely different nature have occurred within a few miles. Land much inferior in intrinsic agricultural value and a few miles farther from the city has been bought up within the last twenty-five years at a very low figure by thrifty farmers with small cash capital, but with large and industrious families, who, by the application of improved methods of agriculture, have succeeded in bringing what were considered as "worn-out" farms up to a high state of productivity, with a corresponding increase in the market value of the land. The extension of good roads, built by the State, has been a factor in this development, but by no means the most important one.

Here we have two movements in opposite directions—rich farms, owned by intelligent, well-to-do American farmers, getting richer, but less productive, but still increasing in market value, due to proximity to the city, sentimental considerations and hopes of improved economic conditions, which will eventually convert them into paying investments, and poor farms becoming rich and productive mainly because they had become so poor, and consequently so low in price, that they were attractive investments for a class of farmers who are in a measure independent of the labor difficulties experienced by their richer neighbors.

Both of these classes have shared in the general increase of knowledge of the underlying scientific principles upon which successful agriculture is based, which knowledge has been brought about largely through the investigations carried on by the United States Department of Agriculture and the various state organizations engaged in the enlightenment of the American farmer.

It is probable, however, that as a broad generalization, the extent to which each class has been able to profit by this knowledge has been in inverse proportion to the amount of knowledge acquired and the intellectual capacity of the farmers. Those families which are but slightly in advance in education and in general intelligence of the peasant classes of the Old World, from which they sprang, can more successfully cope with the sociological and economic conditions with which the American farmers of to-day are confronted than can the more highly educated and intelligent class who have acquired many artificial tastes and refinements which make it very distasteful, if not altogether impossible, for them to conform to the simpler requirements of their poorer neighbors. From these and many other considerations I believe it is safe to assume that the problems most urgently demanding solution by the farmers of western New York are economic rather than agricultural in their nature. What they want to know is how to secure efficient farm laborers to enable them to apply what they already know, or can easily learn, concerning agricultural methods rather than an addition to their fund of agricultural knowledge.

Another serious disadvantage at which the farmers of western New York are placed is that with improved transportation facilities they are coming more and more directly in competition with the West in the staple farm products and with the South in truck crops. They also, in common with the farmers of the entire country, lack organization in the marketing of their crops. Here is another profitable field for the Department of Agriculture. If local shipping associations were organized throughout the entire country on substantially the same basis as the truck growers' associations of Long Island and other truck-growing districts, and these local associations organized into a national association, an immense amount of loss to farmers could be prevented and the consumer would not only be able to procure all kinds of farm and garden produce in much more wholesome and attractive condition, but at less cost than at present. It would take some time, much earnest effort, and the expenditure of considerable amounts of money to effect such a national organization, but it could be accomplished, and when well established it would be not only self-supporting but a source of revenue to the stockholders, and it would be able to so control the production, distribution, and marketing of all kinds of farm produce as to prevent overstocking of markets, loss in transit by reason of products being shipped in bad condition, exorbitant commissions and freight charges, and many other evils which now are a heavy tax upon both producer and consumer.

SOME PHASES OF AGRICULTURAL DEVELOPMENT IN THE MIDDLE WEST.

The last quarter of a century has witnessed the passage from the pioneer stage to a fairly stable agricultural state of an immense strip of fertile country extending from the Canadian boundary on the north to the Gulf of Mexico on the south, and from western Minnesota and Iowa, eastern Kansas, Oklahoma, and central Texas on the east, to western North Dakota, South Dakota, Nebraska, Kansas, and western Texas on the west. During this period some rather curious results have been produced in the way of crop yields, both per acre and per farm. At first it would seem that the opening up of a new country like this would result in constantly increasing yields per acre and per farm of all the staple crops, and that any deviation from this rule would indicate soil depletion. Such, however, is not the case. There are thousands of farms within this area which are not producing as much of any of the staple crops as they have produced at some period since they were first opened up, and yet some of these farms are becoming richer rather than poorer, and very few, if any of them, have suffered soil depletion proportionate to the decreased yields.

Probably a majority of the farmers in this area went in debt, if not for the land itself at least for the buildings and equipment. Every effort was then made to obtain the largest and quickest cash return from the farms in order to pay off this indebtedness as soon as possible. In this effort to get out of debt the farmers spared neither themselves, their families, their laborers, their teams, nor their farms. Everything, from the vital energy of the farmer and his family to the fertility of the farm, was converted into dollars to pay off the indebtedness, or to purchase more land, build more and better buildings, or to buy more or better stock. This stage of development usually marked the maximum production of the more bulky and quickly salable products of the farms, but in comparatively few instances was this maximum production maintained for a long term of years. Sooner or later some combination of circumstances would occur to bring about a reaction. This reaction took many different forms, each individual case being controlled by a somewhat different combination of factors, not the least important of which was the personal equation of the farmer and his family; but whatever form it took, in a large majority of cases it resulted in a decreased output of some one or more of the staple farm products. Sometimes the controlling factor was the depletion of the vital energy of the farmer or his wife; sometimes it was the fact that the goal which the farmer had set out to reach was attained, the farm was paid for, the new house or barn was built and paid for, the additional piece of land had been secured, or some other task which had been undertaken was finally finished; sometimes the need of educational and social advantages for the family caused the farmer to move to town, and to let his farm to a tenant who would not maintain the yields at the standard set by the owner; sometimes, and far too often, the pathetic example presents itself of the farmer and his wife who have worked and struggled and suffered privations and worn themselves out in order to provide a farm home where the family could all be together and the children a comfort and support to their declining years, only to find, when all these sacrifies had been made, that the children would abandon them and leave them with a farm on their hands that they were no longer able to manage without help.

In a good many instances farmers have come to the conclusion that the transportation, grain commission, and packing companies have secured such control of the market prices of all farm products that the margin of profit left for the farmer is so small that it does not pay him to work either himself or his farm to full capacity; so he has adopted the plan of reducing his expenses both of cash and vital energy as low as consistent with a fairly good living for his family, and is simply conserving the resources of himself and his farm until such time as he hopes may come when the farmer will be able to secure a fair share of the profits of his labor.

It would not be a difficult matter to extend the enumeration of the causes which have resulted in decreased farm yields in the Middle West during the last twenty-five years. If, however, I have not already shown that there are many causes other than soil depletion, any further extension of the list would also be equally ineffective. It is not claimed that any or all of the causes are sufficiently general to have actually reduced aggregate crop yields for entire counties or States, but that they are of sufficient frequency to account for the somewhat generally accepted theory that the agricultural resources of this country are becoming rapidly depleted, and they have undoubtedly seriously affected the statistics on the subject.

Another factor that has undoubtedly tended to decrease the average yields, as shown by the statistics of the Middle West, is the fact that much experimenting is being done in attempting to establish agriculture in the semiarid regions where methods have not yet become fully adjusted to climatic conditions, with the result that many very low yields, if not complete failures, are met with.

AGRICULTURAL CONDITIONS IN NORTHERN VIRGINIA.

The agricultural conditions in northern Virginia have not yet recovered from the effects of the civil war, although nearly a half century has elapsed. The former slaves have died or become incapacitated by age, and the younger generation of negroes are very inefficient and unsatisfactory as farm laborers, and their presence tends to discourage the introduction of white laborers on the farms; the result being that labor conditions are even worse here than in the North and Northwest. This portion of the State is producing but a small fraction of what it should. There seems to be an impression that because a large portion of the land is lying idle and yielding no agricultural returns whatever, but is being allowed to grow up to scrub pine and worthless shrubs and weeds, and that because much that is being farmed produces but indifferent crops, that the land is worn out. That such is not the case is, in my judgment, proved by the fact that scattered all over northern Virginia are to be found farms, formerly considered worn out but which have been brought up to a high state of cultivation and are now yielding good returns. The number of these farms is constantly on the increase, and if some solution could be found for the labor problem, it would be quite reasonable to predict that the agricultural production of northern Virginia could be quadrupled within four or five years. It is believed that much the same conditions prevail over a large portion of the entire South.

That the crop yields of all staple products throughout the South are on the increase can not, I think, be questioned, as all available evidence points in that direction. An interesting and significant bit of evidence on this point was secured from an attorney for one of the important southern railroads. I asked his opinion concerning the increase or decrease in crop yields throughout that portion of the South tributary to his road, and he answered immediately and emphatically that there was a marked increase in the yield of all staple farm products, and he went on to state that he had just returned from a meeting of railroad managers where this very point was under discussion, and that after careful consideration of the reports of those who had charge of this question they had come to the conclusion that the yields of all staple crops along the lines of their several roads had been sufficient to warrant them in advancing the freight rates. This was a strong and somewhat unexpected corroboration of the conclusions at which I had already arrived. First, that crop yields are on the increase; and, second, that the transportation companies have better facilities than anyone else for obtaining information concerning any such increase and that as soon as they learn of it they immediately adopt measures to secure to themselves rather than to the farmers any benefits that may come from such increased yields.

UNDEVELOPED RESOURCES, EAST, WEST, AND SOUTH.

Ever since the beginning of American agriculture it has been the custom to refer to "the vast undeveloped agricultural resources of the boundless West." There are still vast undeveloped agricultural resources in the West, but they can no longer be considered "boundless." On the other hand, thousands of eager land seekers and home builders are diligently seeking out every nook and corner of the West that is suited to agriculture, and it is probable that in their eagerness to secure cheap land some of them are attempting to establish homes and farms beyond the bounds of what may safely be considered the agricultural areas.

This tide of pioneers and home builders has been moving steadily westward from the very beginning of American history, and the West has heretofore welcomed them and afforded them with a bountiful hand the opportunities they were seeking. The West will always welcome brain and brawn from the East, and there will always be opportunities there for the right kind of energetic young men and women; but the opportunities to secure cheap land are rapidly decreasing and will at no distant date be little, if any, better than in the East and South. When that time arrives, what is to become of the constantly increasing agricultural population? I predict that it will take the form of a return wave which will bring back to the East and South some of the most energetic and progressive young farmers of the West, who, untrammeled by eastern and southern traditions and customs, will quickly recognize and take advantage of the vast undeveloped agricultural resources of these sections. When that time arrives it will be possible to increase the agricultural production of the country to meet any demands that are likely to be made upon it for many generations to come.

I would therefore sum up my impressions concerning the agricultural resources of the eastern United States, their development and conservation, as follows:

SUMMARY.

1. Crop production per acre is not falling off, but is increasing.

2. The seeming decrease in crop production is generally due to one or the other, or both, of the following causes: (*a*) Changed economic or sociological conditions which have tended to reduce or remove the incentive to maximum production; or (*b*) farmers adopting a more conservative system of farm management which will provide them and their families with a comfortable living with a minimum expenditure of labor—a conservation rather than a dissipation of the potential resources of their farms, with frequently a very marked decrease in the amount of produce sold from the farms, particularly of the more bulky products, such as wheat and corn, which pay a relatively high freight rate in proportion to their value.

3. Agricultural production can best be increased by adopting vigorous measures to remedy faulty economic conditions, and these measures should be directed along the lines of insuring to the farmer a fair share of the price paid by the consumer. This can be accomplished by developing methods of delivering agricultural products as directly as possible from the farm to the consumer in wholesome

and attractive condition, without unnecessary loss or expense in transit and without exorbitant profits to transportation companies and middlemen; and by providing competent and efficient farm laborers at a reasonable wage, including comfortable and attractive country homes.

4. Improved methods of agriculture involve the use of much additional machinery. The manufacture of this machinery is now largely under the control of trusts or combinations which destroy or at least restrict competition and increase the cost to the farmers. Measures should be adopted to prevent such combinations and to insure to farmers an opportunity to purchase all kinds of agricultural implements and machinery at a fair price above the actual cost of manufacture.

5. Liberal appropriations should be provided by Congress and by the several state legislatures for the development of the agricultural investigations now so well under way by the United States Department of Agriculture and by the various state agricultural colleges and experiment stations.

6. No undue effort should be made to stimulate agricultural production until the present faulty economic conditions are corrected, but the campaign for the education of the farmer should be vigorously prosecuted, in order that he may be prepared to meet the demands for increased production when economic conditions have been so corrected that it will be profitable for him to do so.

7. Under proper economic conditions, and with the assistance which will be given him by the United States Department of Agriculture and the state agricultural colleges and experiment stations, if properly supported by liberal appropriations, the farmer will be able to meet any and all demands that are likely to be made upon him for increased agricultural production for many generations to come.

AGRICULTURAL PRODUCTION AS A NATURAL ASSET.

By C. S. Scofield,
Bureau of Plant Industry, U. S. Department of Agriculture.

With comparatively little exception American agriculture is in a condition of transition; that is to say, there are few regions of any considerable extent where any particular kind of agricultural production has been long enough continued to be considered as really permanent. A variety of causes has contributed to maintain this condition, some temporary and others permanent, some economic and some natural, or more truly agricultural. In fact, it would seem that as in the case of our field crops, where a change in the sequence of crops on the same soil has a beneficial effect, so, too, in the type of production for whole regions, a periodic change of some sort has taken place.

As a nation, we have passed through the period when the agricultural production of each region was made as diverse as knowledge and environment would permit, in order to supply local needs, since the transportation of staple products was necessarily expensive. Following there came a rapid extension of agricultural settlement, together with an equally rapid development of means of overland transportation, and this has resulted in a relatively high specialization in crop production, or a localization of crop production to those sections best adapted to the various crops. This tendency toward specialization is now going on at a rapid rate, promoted alike by those agencies which are introducing new crops, and by the zeal of many of our people in seeking crops that will give the quickest and largest returns.

Reactions away from this high degree of specialization are naturally induced by competition in production, by the relatively high cost of transportation, and by the reduced yields which naturally follow the lack of a proper rotation of crops. In looking over any particular section of our agricultural region it becomes apparent that, as regards the kinds of crops and methods of farming, the present condition is essentially temporary. The crops and methods are either newly in vogue or so distinctly unsatisfactory that some change is obviously imperative. Thus the history of our older agricultural sections is a history of the rise and decline of agricultural industries. It is important to keep these facts in mind in making any prognosis of the future of our agricultural productions. As an agricultural people we have not yet "found ourselves."

This being the case, we have as yet no adequate measure for estimating with any degree of accuracy our potential agricultural resources. We hear much of the high productive capacity of the virgin soils of our new regions as compared with that of the worn-out soils of the older regions, but the so-called "exhaustion" of the soils that have been under the plow for one hundred or two hundred years is more apparent than real. It would be difficult, if not impossible, to find any instance of the complete exhaustion of the producing capacity of the soil. It is true that bad methods of farming may render a soil temporarily unfit for profitable production, through the depletion of the supply of organic matter, through ravages of some weed or insect pest, or the ascendency of some plant disease. Any of these difficulties are essentially temporary in character and may be overcome by proper methods of farming.

While it may be true that in time a soil may become unfit for the profitable production of some one crop or group of crops, there is no evidence that any of our once productive soils have as yet become wholly and irredeemably unfit for some kind of profitable agriculture, nor is there any satisfactory evidence of a real irretrievable decline in the productive capacity of any of our truly agricultural regions. Until we have some definite evidence of such a real decline in producing capacity, it will be necessary to accept the conclusion that the productivity of our soils would be maintained indefinitely if a proper sequence of crops and agricultural industries were used.

The relation between the sequence of crops grown on the land and the change in the predominance of industries in a region is necessarily close. Where the sequence of crops is improper, as in the case of the long-continued production of a single crop, or the use in rotation of crops that rapidly reduce the supply of organic matter, the change from one industry to another must come at frequent intervals. If, however, a less destructive system of rotation is followed, so that the producing capacity of the soil for that series of crops is longer maintained, the change from one industry or set of industries to another may be much longer postponed. These facts have been appreciated, more or less unconsciously, by the great body of our farmers. The wisdom of using a rotation of crops and of maintaining the supply of organic matter in the soil is almost universally realized, though, unfortunately, not universally acted upon. When, for one reason or another, one crop or group of crops can no longer be profitably produced in a region, other crops come into use and new industries are established. Owing to this important fact the future outlook is encouraging.

Our greatest national agricultural asset is the character and intelligence of our farmers. If the present high standard of character and intelligence is maintained or improved, the nation need have little fear for the future of its agricultural production. At the present time the mean of our agricultural production is far below the possible maximum, both in gross amount and in yield per area in crop. The present low mean is largely the result of economic conditions. Any material readjustment of these conditions that would require or reward an increase, either in the gross amount of production or in the yield per area, would find an immediate and adequate response. Though the farmers have already done much in using crop rotation, in improving their methods of farming, and in accepting new crops and starting new industries, the end along these lines is not in sight; indeed, only a beginning has been made.

Better rotations are constantly coming into use, better methods of farming are being followed, new and improved crops are constantly finding their places.

The readjustments that take place in our economic conditions must be accompanied by many readjustments in our agricultural production. A higher degree of specialization in crops and methods must be expected in some regions, together with more diversification in others. The facility with which our farmers respond to these economic readjustments, and with which they continue to accept improved methods and more valuable crops, will very largely determine, not only their individual success, but their value to the nation. It becomes, then, a matter of the first importance to insure the maintenance of a high degree of character and intelligence in our farmers. If the future of our agricultural production is threatened, it is through the lowering of the grade of our farmers rather than through the exhaustion of our soil fertility that it is more likely to come.

AGRICULTURAL PRODUCTION.

By W. J. Spillman,
Bureau of Plant Industry, United States Department of Agriculture.

Is crop production per acre falling off? This question must be answered both yes and no. Our study of individual farms leads us to believe that on about 50 per cent of the farms of the country crop production is falling off. The other 50 per cent is about holding its own or increasing slightly. Exceptionally there is a farm on which yield per acre is enormously greater than it was a few years ago. Statistics which have hitherto been gathered on this subject do not reveal the actual status of affairs. These give average yields by States or by counties. They take no account of lands abandoned or put into cultivation, an important factor in many sections. The abandonment of worn-out land and the putting of new land into cultivation may keep up average yields. Nor do statistics reveal the fact that increase in average yields for a given territory is largely due to enormous increases on comparatively few farms, a fact that our investigations reveal to be true. On the whole, the yield per acre of our principal crops has increased slightly for the past two decades, as shown by the following figures:

Average yield per acre for five-year periods.

	Wheat.	Corn.	Oats.	Cotton.
	Bushels.	*Bushels.*	*Bushels.*	*Pounds.*
1891 to 1895	13.4	23.6	29.0	172.3
1896 to 1900	13.2	25.5	23.2	192.4
1901 to 1905	13.9	[a]27.6	33.0	184.6

[a] Owing to the low yield in 1901, on account of the severe drought, this average is made up for the period from 1902 to 1906.

There is no question that on something like half of the farms of this country the yield is less than when the soil was new. The underlying causes for the condition now existing with reference to crop production are easily apparent to the student of agricultural history and methods.

EXPLOITIVE FARMING.

In a state of nature, soils which are well adapted to the growth of vegetation are maintained in a high condition of fertility. Plant roots thread the soil to great depth. When they decay they not only furnish plant food for succeeding generations of plants, but provide humus, which aids in storing moisture and, perhaps, in removing from the soil deleterious substances thrown off by plant roots. In addition, the continual decay of plant roots leaves channels in the soil which open it so as to permit a free circulation of air and moisture. Animal life in the soil adds to its permeability by making burrows. In some sections of country the common fish worm penetrates soils to great depths, making channels which carry down rain water and thus prevent it from flowing off the surface. For these reasons all soils when first put into cultivation, which are well adapted to the production of plants, are highly fertile. Experience in many States has shown that good virgin soils for approximately half a century after they are put into cultivation will produce good crops with practically no attention to renewing their fertility. Under such conditions the farmer, who naturally follows the line of least resistance, will exploit his soil. He adopts types of farming akin to mining, and continues to draw on the resources of the soil's fertility until it is exhausted, before lessening yields compel him to adopt more expensive methods of farming required for maintaining or building up the soil fertility.

On a new and rich soil very little knowledge is required for the production of profitable crops. All that is necessary is to plow, harrow, plant, till, and harvest, which anyone can learn in a short while. Considerable areas of soil are still found in this country from which the fertility has not been completely mined, so that exploitive farming is still practiced with apparent success in some States. These are the more newly settled regions, the most important of which are the Dakotas, the semiarid plains region, and the upper Columbia Basin of Washington, Oregon, and Idaho. In these the original fertility of the soil still suffices for the production of good crops with the most unscientific methods of farming, though in some of them lessening yields are becoming apparent. In some cases the introduction of weeds which are adapted to growing in grain fields have compelled changes in the system of farming, but the change has in the main been from one exploitive type of farming to another. Very large areas of land in this country have now been farmed about long enough to exhaust their original fertility. This is true of the great body of agricultural lands in the Mississippi Valley extending from the Canadian line to the Gulf, and from the Appalachian Mountains to eastern Kansas and Nebraska. The more progressive farmers in this vast area have adopted systems of farming which tend to build up soil fertility. In some sections the change from exploitive to conservative types has been more or less general, in others it is decidedly sporadic.

There are considerable areas, including the territory east of the Appalachian Mountains and most of the cotton-producing States, in which the land has been farmed much longer than was necessary to exhaust the original fertility. In the northern half of the Atlantic coast region the change from exploitive types of farming has been very general and agriculture is on a fairly sound basis, but in the remainder of this region exploitive farming still remains, and crop yields are much less than they were a generation or two ago. There are several instances of exploitive types of farming that have lingered long beyond their legitimate life. These are found on the average cotton farm of the South, in the tobacco fields of Virginia and Maryland, in the corn and wheat fields of southern Illinois, western Kentucky, and southern Missouri, and in the cornfields of the hill country of the South and of northern Arkansas. The great wheat fields of northern California have just reached the point where waning fertility is evident in the low and generally unprofitable yields. The Willamette Valley of Oregon passed through this stage a dozen years ago, and in that section the change to fruit raising, dairying, and other types of live-stock farming are rapidly bringing the soil back to its original fertility.

COMMERCIAL FERTILIZERS.

The early period of exploitive farming usually gives place to a short period of diversification, during which the more progressive element among the farmers experiments with new types of farming, live stock becoming an important factor. In a short while the best forms of live-stock farming for a given locality are determined and more permanent systems of farming are developed. These maintain or increase the fertility of the soil. But the change from exploitive to conservative types is a difficult one to make. The fact has already been noted that exploitive farming requires only a small degree of intelligence on the part of the farmer. On the other hand, any form of live-stock farming requires more constant attention and a very much greater degree of intelligence. Farmers are prone, therefore, to continue the less strenuous system to which they have been accustomed. In the North, where satisfactory grasses and clovers were early found, and where there are no special difficulties in the way of development of live-stock industries, the adoption of conservative types of farming has progressed in a fairly satisfactory way. In the South, on the contrary, several difficulties have been met with, and the development of conservative types has been greatly retarded.

The difficulty of introducing live-stock farming, especially in the South, and to some extent in other sections, has led to a very general reliance on commercial fertilizers. Twenty years ago the use of these artificial manures was practically confined to the Atlantic seaboard. In the northern part of this section it was confined to the more intensive types of farming, like fruit raising and truck growing, in which the maintenance of soil fertility by feeding stock was out of the question. Farther south fertilizers were very early used in the production of ordinary field crops. The use of commercial fertilizers has extended westward during the past two decades in a remarkable manner. They are now used from the Atlantic coast to eastern Kansas, from the Gulf of Mexico to the Ohio River, and to a considerable extent northward as far as Michigan. According to the census of 1900, the value of commercial fertilizers used in the United States was about $50,000,000. At the present time it is estimated that twice this amount is used. So great has become the dependence on chemicals that in some States fully 10 per cent of the value of the crops is expended in purchasing fertilizers. This is a heavy tax on agriculture, and, while it has served temporarily to maintain yields in most cases, it has greatly decreased the profit from farming. In some sections the continued excessive use of fertilizers has led to injury of the soil from the accumulation of the residue left by the chemicals. Some of the truck soils of the Atlantic coast, on which enormous quantities of fertilizers have been used for many years, have become so charged with these residues that they have been abandoned, and large areas of cotton lands are beginning to show injury from the same cause.

SOIL EROSION.

The northern half of the country has always been more or less covered with various grasses. These have prevented soil erosion except in small isolated areas; but in the South, where a single-crop system with clean culture has been the rule, and where, in consequence, the soils have been left bare during the winter, soil erosion has been an important factor, especially where the land is more or less rolling or hilly. In some sections erosion has proceeded to such an extent that considerable areas have been abandoned.

ECONOMIC CAUSES.

Exploitive types of farming, as already stated, require less knowledge than the more complex types which provide for maintaining soil fertility. Not only that, but they require much less capital. The equipment of an ordinary cotton farm in the South, including buildings, live stock, and implements, does not exceed $10 per acre. On an ordinary grain farm in the West the corresponding equipment amounts to approximately $20 per acre. On a well-equipped hay farm, $40. On the other hand, a properly equipped hog farm must have about $70 per acre expended in buildings, fences, live stock, and machinery in order to put it in condition to return a maximum income. A good dairy farm requires $100 an acre for equipment, and the highest class dairy farms in this country have had $300 per acre thus expended. It is natural, therefore, when we remember that a large part of the West has been settled by pioneers without capital other than their energy and intelligence, that these cheaper types of farming should develop. It is also characteristic for men to live up to their income, hence it is that a change to higher types of agriculture has been retarded by the difficulty of securing sufficient capital. The development of agriculture has, therefore, been retarded both by lack of capital and by the fact that the change from exploitive to conservative types of farming requires knowledge which the average farmer does not possess. In the South special difficulties have existed. In the first place, the prevalence of the cattle tick has made beef production and dairying very precarious. The warm climate has also added greatly to the expense in the handling of milk. Not only that, but the available labor of the South has not been of a type that could easily be taught the management of stock, nor could it be relied on to give that constant attention necessary to success with any class of farm animals. As a result exploitive types of farming have continued in this section long beyond the time when they yield a fair return to labor. This is one reason why the use of commercial fertilizers has extended so much more rapidly in the South than it has in the North.

SHALLOW PLOWING.

In all sections of the country where farming has continued so long that exploitive types of farming are no longer profitable, the decreasing fertility of the soil and the consequent impoverishment of the farmer has led to the use of inferior draft animals, with resulting shallow plowing, so that in many sections only 3 or 4 inches of the top soil is now utilized.

NEED OF INCREASED CROP PRODUCTION.

During the past century the increase in the area of cultivated land in this country has, in general, kept pace with increased demands for farm products, and in some instances has even exceeded these demands. In the case of the wheat crop this is still true. In recent years the lands which have been brought into cultivation have been mainly wheat lands. The average crop of wheat produced during the five-year period from 1895 to 1900 was 540,000,000 bushels. During the next five-year period the average was 660,000,000 bushels, an increase of 22.2 per cent. During the same period the population increased only 9.2 per cent, but during this same period wheat exports decreased over 23 per cent. The increase in the production of corn was slightly less than the corresponding increase in the population. Not only has there been a large increase in area of wheat land in this country in recent years, but there has been a similar increase in other countries, especially in Canada and in Argentina. It is probable that the increase in area of available wheat land will continue for some years to meet increased demands for this cereal, but in the case of corn, the most important crop in this country, conditions are different. For the past few years the increase in the area of corn has not kept pace with the increased demands for this cereal. As a result the price of corn has been higher during the past five years than during any similar period in the history of this country, even with the record-breaking crop of 1906. With the exception of the wheat crop, there is no question that future increases in demand must be met largely by increased yields per acre, and ultimately the same will be true even of wheat. The supply of easily available farm land in this country is well-nigh exhausted. Irrigation projects in the West may add a few million acres and drainage of swamp lands will ultimately add several million acres, but these additions will hardly meet the increased demands for the present and not at all those of the future.

It is fair to assume that the demand for farm products will continue to increase approximately at the present ratio for the immediate future, at least until population begins to press upon the food supply. With practically all of the easily available farm land already in private hands, it is evident that future needs must be met by increased yields per acre. Can this be done? That we shall ultimately reach a condition under which the power of the soil to produce crops can not be made to meet all demands on it seems reasonably certain, but not imminent. When we remember that the average yield of corn in this country is less than 30 bushels per acre, while on the best farms it is more than 100 bushels; that the average yield of wheat is only about 15 bushels, while on many farms it is more than 30 bushels; that the average yield of cotton is two-fifths of a bale, while on many farms it is 1½ or 2 bales, it would appear that with our present area of land it would be possible, by the most approved systems of farming, to feed and clothe twice our present population without requiring too much of the farm. It would probably be possible by united and intelligent effort to double the yield of every important crop in this country. This has been done in the older countries of Europe. In fact Germany, France, and England to-day, on lands farmed many centuries, produce yields practically double those in this country. For instance, the average yield of wheat in bushels per acre in these countries for the period of 1897 to 1906 is as follows: Germany, 28; France, 19.8; and England, 32.2; while the yield for the United States is only 13.8. But to bring about these increased yields exploitive types of farming must be utterly abandoned and in their place types must be developed that provide for maintaining and building up the fertility of the soil. It is no small task to bring about such a revolution in methods of farming.

The point has already been made that conservative farming requires more capital, more expense in operation, and a higher degree of intelligence on the part of the farmer. It also requires better systems of management. How then shall we bring about these better systems of farming which, in the near future, will be necessary to meet the demand for farm produce in this country?

BETTER TYPES OF FARMING.

In the first place, types of farming that maintain or increase soil fertility must be more generally adopted. This means the extension of the various types of live-stock farming and a decrease in the area devoted to crops for sale. It is evident, therefore, that the extension of live-stock farming alone will not meet the conditions. We must, therefore, depend more and more largely upon other means of building up soil fertility. Experience has shown that dependence can not be placed on commercial fertilizers alone. Their indiscriminate use, without attention to the humus content of the soil, has not proved to be satisfactory. Not only that, but the supply of some of the chemicals which have been relied upon in the past to maintain crop yields is not inexhaustible. Practically our whole supply of potash is obtained from a single locality in Germany. The mines which supply this material will undoubtedly be exhausted in the not distant future. The major part of our supply of phosphorus comes from material mined along our South Atlantic coast. As time goes on the supply of phosphorus decreases, and undoubtedly we shall soon reach a period when increased demand and decreased supply will result in a rise in price that will render the use of phosphates less profitable than at the present time. The problem, therefore, is an exceedingly complicated one; even when we exhaust our knowledge of the possibilities in the matter of increasing soil fertility we have not fully met the conditions. This means that scientific investigation on behalf of the farmer, especially as relates to the maintenance of soil fertility, is not yet finished. It is highly important that these investigations should be extended and that encouragement should be given to those who are trying to solve the problems of soil fertility. It is known that much can be accomplished by the growing of cover crops to be turned under for the production of humus. Especially is this true of the legumes, such as cowpeas, soy beans, the vetches, and the clovers. These not only add humus, but because of their power of utilizing atmospheric nitrogen they store in the soil great quantities of nitrogen, the most expensive of all plant foods. The use of such crops, together with a moderate use of commercial fertilizers, greatly enhances the producing power of the soil, and in sections where live-stock farming can not be developed. The farmer must be taught how to use crops of this character. It is seen that the problem is, therefore, largely one of teaching the farmer systems with which he is to a large extent unfamiliar. How shall this be accomplished?

FARM PRACTICE INVESTIGATIONS.

Many of the principles involved in crop production have been worked out through investigations of scientists. On the other hand, practically every intelligent farmer is more or less of an experimenter. There is a vast fund of knowledge in possession of individual farmers of this country, but, generally speaking, the farmer makes no record of his results, and the experience of one farmer is of comparatively little benefit to another. To meet this condition the United States Department of Agriculture has undertaken the investigation of farm practice in all sections of the country. The experience and results of the most successful farmers are collected and correlated, thus adding enormously to our store of knowledge concerning the elements of success in farming. It is fair to assume that half of the growing science of farming, in so far as it has been formulated, is the result of practical experience on the farm; the other half is the result of scientific investigation. While there are many problems yet unsolved, one of the main problems at the present time is how to get knowledge already in our possession into the hands of the farmer. Frequently the problem of the farmer in introducing an important principle into his operations is fully as great as that of the scientist who discovered the principle. There is need, therefore, of a central agency which shall be in intimate touch with the scientist and with those farmers who have worked out important problems, on the one hand, and with the main body of farmers who need information about better systems of farming and better farm methods, on the other. The problem here is that of bringing home to the people the work of the State to aid the farmer. Many agencies are available in this work. The bulletins issued by the States and by the National Department of Agriculture are of much value. The farmers' institutes reach a large number of farmers, and the agricultural press disseminates information; but when all is said and done the fact remains that the average farmer is not in the habit of getting his information from the printed page. He gets it from observation. Not only that, but, as before stated, it is frequently a difficult matter to make use of information, because to do so requires radical changes in the system of farming. An important means, therefore, of getting information into the hands of the average farmer is that of the itinerant teacher. Not only does he become acquainted with the people, thus gaining their confidence, but he learns their problems and he knows the information they need. Direct personal contact is an important factor in influencing the farmer to change his system.

The farmer must be taught how to plan his work with a view to better utilization of farm labor. During the past few years labor has been exceedingly scarce and only those farmers who could give employment the year round have been able to secure sufficient labor to carry on their work properly. Fundamental studies are necessary in order to determine the relation of various types of farming and rotations of crops to the needs of labor at all seasons of the year. These studies are being made by the Office of Farm Management in the Bureau of Plant Industry. The farmer must be taught proper methods of fertilization, improved methods of cultivation; he must be taught the principles of drainage, and in sections where soil erosion is imminent, or is taking place, he must be taught how to prevent it by deep plowing and an abundant supply of humus, and in extreme cases by contour cultivation or by terracing.

IMPROVEMENT OF CROPS.

In addition to better systems of farming and better methods of fertilization, cultivation, etc., much can be done to increase the yield of crops by the introduction of better varieties and by the improvement by breeding and selection of the varieties already at hand. Abundant investigation has shown that an increase of 25 per cent in the yield of our common crops can be produced by the selection of individual plants having high yielding power. There is an especial advantage in this method of increasing crop production in that the use of improved seeds does not require any higher intelligence than the use of ordinary seeds. This is especially true of new varieties of fixed type which are of superior merit, for when the farmer once secures a small amount of the seed of such a crop he obtains a permanent increase in yield, even where his methods are not changed at all.

ACCIDENTAL LOSSES.

The yield of nearly all crops in this country is decreased to a considerable extent by the ravages of insects and by fungous diseases. These are in many cases preventable. The methods required, however, call for considerable intelligence, and constant effort is necessary to get the farmer to use them. It is a legitimate function of the State to teach the farmer the use of remedies for these pests.

It will not suffice to maintain agricultural production merely to teach one generation of farmers how to farm. The personnel of the farming community is continually changing. New men embark in the business and young men grow up to assume the duties of their elders. These new farmers must in the main be taught over again the lesson learned by those who preceded them. The task of teaching the farmer will, therefore, never be finished. It is abundantly demonstrated, however, that when the task is properly done, the soil at present available in this country may feed and clothe a population enormously greater than that which it now does.

INTERPRETATION OF CROP STATISTICS.

By Dr. A. C. True,

Director of Office of Experiment Stations, U. S. Department of Agriculture.

Although the data show an increase in the average yield of different crops for the ten years, 1897–1906, as compared with the average for the forty years, 1867–1906, they do not necessarily indicate an actual increase in the amounts of plant food in the soil, taking the country as a whole, nor do the average low yields for certain periods definitely mean a decrease in the quantity of plant food at those times. It is to be expected, however, that in certain sections this natural resource has diminished through improper management, but the depression is entirely obliterated in the average figures by conditions and circumstances incident to the development of new regions and not infrequently by accidental climatic conditions and other forces.

In the interpretation of the crop statistics for the last four decades a number of factors must be considered. Some of these are general, while others are local and incidental. The influence of our agricultural experiment stations is limited to the twenty years since they became generally established. In most States agricultural colleges have not been well established longer than the experiment stations, while farmers' institutes and other agricultural extension work are of a still more recent date. The agricultural short courses and winter courses, which are now attended by thousands of farmers and farmers' sons, are the development of comparatively recent years. In fact, many of the factors just mentioned can have had an effect on crop production only during the last ten or fifteen years. The principal forces with a bearing on crop yields are the works of the United States Department of Agriculture, agricultural experiment stations, agricultural colleges, farmers' institutes, and state boards of agriculture, the agricultural press, the better adaptation of crops to the conditions of soil and climate by seedsmen and plant breeders, the more liberal and more rational use of fertilizers, better methods of farm management, especially in the diversification and rotation of crops or the introduction and substitution of kinds and varieties of crops in particular sections, the progress in the improvement of agricultural implements, and the increase in the value of the crops and of the land.

All these influences are now widely operative in the United States and undoubtedly are doing much toward the general improvement of our agriculture and the maintenance of soil fertility.

Other factors of wide influence, however, affect the average crop yields of limited periods, and these must be taken into account in the analysis of crop statistics. This is decidedly the case in the periods now under consideration. For example, in considering the average yields for the different decades account must be taken of the fact that during the period of 1897–1906 the number of good crop years was greater than in the preceding decade. Statistics of this department show that from 1887–1896 the average yield of corn was low in 1887, 1890, and 1894; of wheat in 1888, 1890, and 1893; of oats in 1890 and 1893; of barley in 1887 and 1894; of rye in 1887, 1888, 1890, and 1892; of buckwheat in 1887 and 1888; of potatoes in 1887, 1890, 1892, and 1894; and of hay in 1887, 1890, 1891, 1892, 1894, and 1895; while from 1897–1906 they indicate a low average yield of corn only in 1901, of barley in 1900, and of potatoes in 1897 and 1901. This fact contributes as much, if not more than any other, to the reduction of the average yield for the decade of 1887–1896 and the very perceptible increase for the decade 1897–1906. An almost unusual succession of good crop years in the last decade has had its effect in bringing the average for this period above the average for forty years. Undoubtedly some of the larger average yields in the first decade here considered are due to the fertility of new lands, while some of the reduced average yields of later periods may be due to a decline in fertility in some of the older farming regions. The universal custom in new regions has been the continuous taking of crops from the soils without putting anything back in the way of manure, etc.

A strong incentive to farm with greater care and thoroughness is the increase in the value of farm lands and farm products and the consequent increase in land rents. On the one hand, greater returns are required to maintain the rate of income on the present valuation, and, on the other, the enhanced value of the products, together with the rapid decrease of new lands suitable for agriculture, makes it incumbent upon the farmer to use more care and skill in his work.

By considering each crop separately the effect of some of the principal influences tending to raise or to lower the average yield may be brought out more clearly. The increase in the average corn yield per acre in the northeastern part of the country, from Maryland to Maine, has been due, among other things, to the extension of the dairy industry in that section. In dairying, the grain and roughage produced on the farm are fed to the cows and the comparatively large quantities of manure produced are returned to the soil, with the result that the fertility and consequently the average yield is brought up. Furthermore, in the New England States farmers in certain sections are beginning to grow the higher yielding Dent varieties of corn in place of the Flint varieties. Throughout the corn belt seasons have been quite favorable in recent years. The methods of cultivation, largely due to experiment-station work, have been improved, and as a result of station and extension work a much more rational selection of seed corn is practiced. This is noticeably true in Indiana, Illinois, and Iowa, where the average yield has considerably increased during the last decade. The high average yields of earlier periods are probably due largely to the initial fertility of the soil. It is also a fact that as some of the States were settled the best lands were first brought under cultivation, and therefore the average yields are highest in the earliest decade. Kansas and Nebraska and all of the States of the plains were first settled along the river valleys in their eastern parts, where both soil and climatic conditions were most favorable, and for this reason the average yield of crops for this period shows up well, while later on, when settlers worked westward and were obliged to take greater risks, especially with reference to precipitation, the average yields naturally decreased. This condition makes it extremely difficult to definitely interpret crop statistics for the States which were settled during this period. In this case the lower average yields of later decades do not indicate a reduction of fertility. The statistics for corn bring out this fact better than those for wheat, because corn was not so subject to the attacks of the chinch bug in some of the earlier periods.

Wheat production has been very favorably influenced by the introduction of varieties better adapted to certain regions. The durum wheats, introduced by this department since 1900, have proven to be drought and rust resistant, outyielding most spring varieties in dry seasons. About 50,000,000 bushels were grown in 1907, which represents more than one-twelfth of the entire wheat production of the country for that year. In addition the winter wheat area, through the introduction of hardier types, has been extended farther north, this being particularly true in Nebraska, and to a lesser extent in Iowa. In this section winter wheat usually yields better than spring wheat, while the average yield of spring and winter wheat for the whole country shows but little difference. In nearly all those States in which dry farming and irrigation are practiced, the average yield of wheat has gone up, mainly because these methods of farming are becoming better understood, or, in other words, the farmer has become more efficient in the utilization of the plant-food resources present in the soil. In some of the older and principal wheat-producing States where up-to-date methods are in use and where wheat improvement has been carried on by experiment stations and other agencies, the average yield has declined, but this may be taken as showing that on the one hand the soil fertility has gone down, while on the other the opposing factors have not been quite efficient enough to overcome the decline in yield due to this cause.

The same statements in general may be made in regard to oats and barley, and attention may be called to the figures given for Montana, Idaho, Utah, and Washington. These remarkable increases in the average yield do not mean that more available plant food has been added to the soil, but that more finds its way into crops because of improved and more efficient methods. In Wisconsin, Manshury barley, introduced and disseminated by the experiment station, has become the standard barley of the State, and has proved a very practical barley for the Northwest. This is evidently one of the principal factors which has brought up the average yield, almost 4 bushels per acre during the last decade.

The data on potatoes hardly admit of general conclusions. This crop is frequently neglected when other lines of work are more profitable, and especially when the farmer aims to grow enough for his own use only. In some of the Eastern States, for instance, where the dairy industry has recently made such rapid strides, the potato crop, and especially commercial potato growing, has fallen out of favor to some extent and a loss of average yield has been sustained. The high average yield in Maine for 1897–1906 is principally due to the development of the Aroostook County potato-growing region of virgin soil. The Maine Experiment Station has been of very material assistance in bringing into use more rational methods of applying fertilizers and establishing the practice of spraying against potato diseases.

In summarizing, it may be said that the data presented in the tables show how the average yields for any given period may vary as compared with those of another period and that the crop-producing power of our soils, taking the country as a whole, during the last forty years has not decreased. The explanations given above are not complete, as they suggest only briefly in what ways different factors may be active. The campaign of agricultural education, continuously carried on by this department, the agricultural experiment stations, agricultural colleges, and other means of agricultural instruction, has for its object the improvement of agricultural conditions in general, and this is largely brought about by increasing or at least maintaining the crop-producing power of the land. In reviewing results, however, it is impossible to say exactly how much credit is to be given to each factor, as data are not to be found from which such conclusions might safely be drawn. Further, the variation of the average yields between different periods can not be interpreted as meaning a corresponding decrease or increase in the amount of available plant food present in the soil.

During the past decade the American farmer has been stimulated and encouraged by generally favorable weather and rising prices for farm products. At the same time he has had the aid of a system of agricultural education and research, organized under national and state auspices, which for the first time in the history of this country has become widely diffused and broadly efficient. Agriculture under these conditions has rapidly improved and become a hopeful and progressive industry. The problem now is to diffuse agricultural education so thoroughly and effectively that the great mass of our farmers will be able, even under more adverse conditions, to more than hold their own in the world's competition and maintain unimpaired the fertility of our soil for the benefit of succeeding generations.

THE CONSERVATION OF THE FERTILITY OF THE SOIL.

By Dr. H. W. Wiley,
Chief of Bureau of Chemistry, U. S. Department of Agriculture.

In compliance with the request of the President of the United States, I offer to the commission appointed for the conservation of our natural resources the following observations upon the conservation and increase of the fertility of the soil.

This is a problem which has from the earliest times been of interest to all persons connected with agriculture. In 1788 the Philadelphia Society for Protecting Agriculture, recognizing the importance of this problem, took steps to secure a proper discussion of it. This society offered premiums for the discussion of certain problems relating to agriculture, among which I may mention the following:

> III. For the best method of counteracting the injurious effects of frost, in heaving or spewing up ground and exposing roots of wheat to the drying winds of the spring, founded in experience, a gold medal, and for the second best a silver medal. The account to be presented to the society by the 20th of December next.
>
> V. For the best method of recovering worn-out fields to a more hearty state, within the power of common farmers, without dear or far-fetched manures; but, by judicious culture, and the application of materials common to the generality of farmers, founded in experience, a gold medal; and for the second best a silver medal. To be produced by the 20th of December, 1788.
>
> VI. For the best experiment, soil and other circumstances considered, in trench plowing, not less than 10 inches deep, and account of the effects thereof, already made or to be made, on not less than one acre, a gold medal; and for the second best a silver medal. To be pro[illegible]ed by the 20th of December, 1789.
>
> VII. For the greatest quantity and variety of good manure, collected in one year, and best managed, from materials common to most farms, regard to be had to the proportion and goodness of such manure, and the quantity and goodness of the arable and grass lands of the whole farm on which it is obtained, a gold medal; and for the second best a silver medal. To be claimed by the 20th of December, 1789.
>
> XI. For the greatest quantity of ground, well fenced, in locust trees, or poles of the sort used for posts and trunnels, growing in 1789, from seed sown after this time, not less than one acre, nor fewer than 1,500 per acre, a gold medal; for the second best, a silver medal. To be claimed in December, 1789.
>
> XIV. For the best method, within the power of common farmers, of recovering old gullied fields to a hearty state, and such uniformity or evenness of surface as will again render them fit for tillage; or, where the gullies are so deep and numerous as to render such recovery impracticable, for the best method of improving them, by planting trees or otherwise, so as to yield the improver a reasonable profit for his expenses therein, founded on experiment, a gold medal; and for the next best a silver medal. To be produced by the 1st of January, 1790.

From the above list of problems submitted for discussion it will be seen that the importance of the conservation and increase of the fertility of the soil was thoroughly recognized at that epoch. The prospectus stating the problems to be discussed was issued by the society over the signature of its secretary, Samuel P. Griffitts, on the 5th of February, 1788. The prospectus was published in the Columbian Magazine for February, 1788. I have not yet been able to find any printed copies of the answers to these problems, although I am still on the lookout for them. It would be of the greatest interest at the present time if the views which were entertained immediately subsequent to the Revolutionary war on this important subject could be considered, and later on I have given a summary of them. In the further consideration of this subject I will first call attention to the problem of washed soils.

In 1894 I embodied in Farmers' Bulletin No. 20, in collaboration with the divisions of Soils, Forestry, and Botany, my ideas of the best methods of recovering washed soils. The part which I contributed en bloc is found on pages 7–11, which is as follows:

> Along the banks of the Ohio River and in very many portions of the South hundreds of fields that were once covered with sturdy forests of oak, maple, walnut, and pine, and which bore under cultivation, after being cleared of the natural growth, large crops of wheat, maize, tobacco, and cotton, may now be seen furrowed with gullies as with the wrinkles of age, and abandoned to brush and briers.
>
> A surface layer of good agricultural soil 6 inches deep resulting from the slow and gradual disintegration and decay of rocks and accumulation of humus may have required hundreds of years for its natural formation, and yet it is liable to be washed away in a single storm.
>
> This excessive erosion, or washing, of lands may be prevented, and the already gullied fields may be recovered, and steep slopes of loose material may be held and prevented from washing—
>
> (1) *By chemical means*, in the application of manures and fertilizers and in the accumulation of organic matter, which change the texture of the soil and make it more porous and more absorbent of water, so that there is less to run off over the surface.
>
> (2) *By means of cultivation and underdrainage*, which prevent erosion by distributing the surface flow over the ground and increase the amount carried off by underdrainage.
>
> (3) *By reforestation*, or the planting of trees, which act mechanically to prevent washing.
>
> (4) *By grass and similar vegetation*, which bind the soil grains and prevent their washing away.
>
> The erosion of a soil is caused by the wearing of the rain and snow waters which can not penetrate into the soil fast enough to be carried away by underdrainage, and which, by reason of the slope or contour of the land, run off over the surface, carrying along particles of sand and clay. When this water accumulates in a depression in the field the force of the torrent may be sufficient to cut out a great gully in a short space of time.
>
> The extent of washing to which the soil is exposed depends upon the quantity of rainfall in a given time, the slope or contour of the surface, the texture of the soil, the vegetative covering of the surface, and the kind and condition of cultivation. A soil composed chiefly of moderately coarse grains of sand, and having good underdrainage, will absorb the heaviest rainfall without much danger of surface erosion. A clay soil, on the other hand, into which the water can not percolate with anything like the rapidity of the precipitation will be washed and gullied by the torrent of water which must flow over the surface.
>
> ### CHEMICAL RELATIONS OF THE SOIL TO SURFACE WASHING.
>
> It has been repeatedly shown by experiments and by the experiences of farmers that a soil, as a rule, absorbs water more readily as the content of organic matter and of humus increases. Surface erosion can, therefore, be largely prevented by such a system of cultivation and cropping as will introduce as large a quantity of organic matter into the soil as possible. A very old method

> of recovering washed and gullied land is to place straw in the furrows while plowing, the straw not only acting mechanically to hold the soil in place and prevent surface erosion, but also in a very efficient way to increase the quantity of humus, thus making the soil hold large quantities of water which otherwise would have passed off over the surface. In this simple way fields which have been badly washed and gullied and entirely abandoned may be recovered and made highly productive.
>
> The most important thing in the recovery of waste fields is the incorporation of organic matter of some kind in the soil; pea vines, stubble, briers, or leaves from the forest may be used as a source of the organic matter. The straw from one acre of land which has been recovered, as mentioned above, will be sufficient to start the recovery of another acre, even if this be deeply furrowed with gullies. Where enough organic matter can be used as a surface dressing, this layer helps greatly to retain water and to make the underlying soil more absorbent.
>
> As soon as a sufficient supply of humus has been accumulated and the lands are brought up to an adequate condition of fertility, clover or grass should be seeded, if the land is at all suited to these crops, or rye, oats, or field peas should be sown to help hold the surface. Little by little, but more rapidly than would be expected from the forbidding aspect of the field, the land can be reclaimed again and made productive through the accumulation of humus and organic matter. A soil containing a fair quantity of humus will wash less readily than one nearly destitute of this matter.
>
> A soil containing a fair supply of lime is much less liable to wash than one similarly situated and exposed which is deficient in lime. The reason of this is that clays which are deficient in lime, when once brought into suspension by moving waters, will remain in suspension and keep the water turbid for a long time. Clays which are heavily impregnated with lime salts, on the other hand, are in a flocculated state, the fine grains of clay being held together and in contact with the larger grains of sand. This flocculated mass quickly settles and is originally not so easily disturbed and carried off by moving water. A field treated with an abundance of lime is thus less easily washed by heavy rains. The results of investigations by Schulze, Schloesing, and Hilgard have shown in a most emphatic way the beneficial changes which take place, especially in stiff clay soils, by the application of lime.
>
> The change in the physical condition of the soil which is produced by the lime, and which is likewise produced by a number of other chemicals ordinarily used in commercial fertilizers, is another important factor worthy of consideration. A stiff clay soil is practically impervious to the penetration of surface water when it is delivered in such torrents as we are liable to have in our summer storms. A well-limed soil, on the contrary, although it may contain as much clay but in which the particles are flocculated or drawn together, is much more pervious to water, and the amount of water which the soil will carry down through underdrainage is increased, and the excess which has to flow off over the surface is diminished. The surface washing of cultivated fields, especially those which are naturally deficient in lime, can be greatly diminished, therefore, by the free application of this substance to them.
>
> A number of the ordinary fertilizing materials have an important effect upon the texture of soils and upon the permeability of soils to water, but few systematic investigations have been carried on in this line and not much, except of local importance, has been definitely settled by experiments or by the experiences of farmers.

From the above it is seen that the problem of washing may be partly controlled at least by the chemical treatment of the soil in such a manner as to render the particles more adherent and tenacious and less liable to disintegration under the action of rain. The tendency to wash may also be largely overcome, except in case of excessive rainfall, by deeper tillage. If the hard underlayer of the soil on the hillside could be broken and softened to the depth of from 12 to 18 inches the quantity of water which would be retained by the soil before starting to run would be greatly increased and thus the amount of washing would be to that extent diminished. Only those who have lived in localities in which the soils are subject to washing, as I have, can realize the great importance of making efforts to counteract it. The methods of holding the soil by grass and by various trees are, of course, the most effective, but these take the soil away from tillage and thus, to a certain extent, restrict the farmer's activities in the growth of ordinary field crops. The contour method of tillage is also a great aid in this respect, and it should always be resorted to in connection with chemical and mechanical means of avoiding erosion. By careful attention to details of this kind it is easy to see that large areas may be restored to tillage which have been virtually abandoned and allowed to grow up in brush and briars.

In an address delivered before the American Association for the Advancement of Science, Section C, in 1886, I discussed the economical aspects of agricultural chemistry. This discussion was largely in the line of the conservation of plant food, which was made the subject of another discussion at a later period, as I shall mention further on. Without attempting to recapitulate here the statistical data on which the argument is based, I will call attention to some of the principal conclusions reached in this discussion. It was shown that the total value of plant food—that is, potash, phosphoric acid, and nitrogen—removed from the soil in the agricultural crops of the United States at that period had a market value of three and one-third billion dollars. Of course the market value at the present time has increased not only in proportion to the crops but also in actual cash value for the ingredients mentioned. In commenting upon this point I said:

> These quantities of plant food removed from the soil annually seem enormous, but it must be remembered that they are not all lost; much of them is left in the soil, in roots, straw, stalks, etc. Those, however, who are acquainted with the method of farming practiced in the newer parts of our country know that cornstalks and straw are generally regarded as nuisances, to be removed as easily and speedily as possible. It is not tilling the soil, but killing it, that is practiced. Stables are removed to get out of the way of the accumulating manure, and the cornstalks are raked together and burned to prepare the field for a new crop. True, in many localities the waste of such a proceeding, especially in nitrogen, is understood. Yet it must be confessed that over vast areas of our agricultural lands there is no conception of the idea of possible exhaustion of the soil, and no systematic method of preventing it. The refuse of the crop, the straw, the stalks, etc., are put out of the way as easily and quickly as possible, and without thinking of the robbery which is thereby committed.
>
> The stores of plant food which have accumulated in our virgin soils are indeed great, but they can not withstand this constant drain on them. The effects of this system of culture soon show themselves in diminished yield, as is seen in the great wheat fields of the Northwest and of California, which do not produce at the present time more than half the crop at first obtained from them.

It is interesting to note that at that time, in 1886, long before the discovery of the rôle of leguminous plants in producing nitrification, the importance of this process was fully realized in agriculture. I say on page 21:

> It would not be proper to take time here to enter into a detailed discussion of the process by which organic nitrogen, or nitrogen of any kind, is converted into nitric compounds, a process which is of the utmost importance to vegetable growth and which it is now generally conceded is due to a kind of fermentation set up by a special organism. Thanks to the results of the patient and fruitful investigations of Pasteur, it has been possible to secure pure cultivations of this nitric ferment. Perhaps the chief credit of this achievement is due to Schlosing and Muntz,[a] but the part taken in it by Warrington, Berthelot, Deherain, and Joulie must not be forgotten.

---

[a] Comptes rendus, Vol. LXXXIV, pp. 301 et seq., and Vol. LXXXIX, pp. 891 et seq. and 1074 et seq.

The dangers which were to be apprehended from denitrification were also fully set forth at that time, as will be seen by the following quotation:

> A process directly the reverse of nitrification has also been observed by Gayon and Dupetit,[a] by which nitrates are destroyed by a denitrifying ferment. This ferment is described as an anaerobe. It acts most vigorously at a temperature of from 35 degrees to 40 degrees, and the experimenters, under favorable conditions, succeeded in totally decomposing a 5 per cent solution of nitrate of potassium. Heat, chloroform, or sulphate of copper sterilized the solutions; but carbolic and salicylic acids do not interfere with the fermentation, on the contrary, are themselves decomposed, like organic matters. The gas evolved is pure nitrogen, representing a large portion of the nitrogen originally present in the nitrate. The rest of it forms ammoniacal compounds.[b]

Again, on page 32, I say:

> In the light of the investigations of the last few years it may be well to admit that the opinion held by the vast majority of agronomists and agricultural chemists and physiologists, that the free nitrogen of the atmosphere never is assimilated by the growing plant, should be held open for revision.
>
> The general belief among scientific men who have paid attention to this matter has inclined to the opinion of Lawes and Gilbert, Pugh, and Boussingault that the growing plant does not in any circumstances assimilate the free nitrogen of the air. So widespread was this opinion that before the investigations just noticed, when Atwater[c] published a series of experiments showing the contrary, it was thought some factor in the investigation had been overlooked. According to Atwater's results it appears that "the plants grown in nutritive solutions exposed to the air, but protected from rain and dew, contained at maturity much more nitrogen than was supplied them in nutritive solution and seed."
>
> This is certainly a definite and unequivocal statement, and it was followed by "for this excess of nitrogen there was but one possible source, namely, the atmosphere."

All these elements in the conservation of the plant foods in the soil naturally must be construed in connection with the food supply of man himself, and this led to the following observation in the paper read in 1886, as follows:

> Since with a proper economy the natural supplies of potash and phosphoric acid, as we have seen, may be made to do duty over and over again and last indefinitely, the economist who looks to the welfare of the future need have no fear of the failure of these resources of the growing plant. Indeed, it may be said that the available quantities of them may be increased by a wise practice of agriculture based on the teachings of agricultural chemistry.
>
> But with the increase of population comes an increased demand for food, and therefore the stores of available nitrogen must be enlarged to supply the demands of the increased agricultural product. It is certain that, with the new analytical methods and the new questions raised by the investigations of which I have spoken, many series of experiments will be undertaken, the outcome of which will definitely settle the question of the entrance of free nitrogen into vegetable tissues. If this question be answered affirmatively, agricultural science will not place bounds to the possible production of foods. If the nitrifying process does go on within the cells of plants, and if living organisms do fix free nitrogen in the soil in a form in which at least a portion of it may be nitrified, we may expect to see the quantities of combined nitrogen increase pari passu with the needs of plant life.
>
> Thus even intensive culture may leave the gardens and spread over the fields, and the quantities of food suitable for the sustenance of the human

race be enormously increased. In regarding the agricultural economies of the future, however, it must not be forgotten that a certain degree of warmth is as necessary to plant development as potash, phosphoric acid, and nitrogen.

If it be true, therefore, that the earth is gradually cooling there may come a time when a cosmic athermacy may cause the famine which scientific agriculture will have prevented.

Fortunately, however, for the human race, the cereals, the best single article of food, are peculiarly suitable to a cold climate. Barley is cultivated in Iceland, and oatmeal feeds the best brain and muscle of the world in the high latitudes of Europe.

It is probably true that all life, vegetable and animal, had its origin in the boreal circumpolar regions. Life has already been pushed half-way to the equator, and slowly but surely the armies of ice advance their lines. The march of the human race equatorwards is a forced march, even if it be no more than a millimeter in a millennium.

Some time in the remote future the last man will reach the equator. There, with the mocking disk of the sun in the zenith, denying him warmth, flatheaded and pinched as to every feature, he will gulp his last mite of albuminoids in his oatmeal, and close his struggle with an indurate inhospitality.

The waste and conservation of plant food was studied in a systematic manner as applied to soil fertility in my address as retiring president of the American Chemical Society at the Baltimore meeting of the Society on December 27, 1893. The problem which was presented at that time was stated in the following language:

One of the greatest of the practical problems presented for solution by agricultural chemistry is the conservation of plant food. With an abundance of plant food and a favoring climate, it is difficult to place a limit to the power of the earth for supporting life. We have read much in political economy of the limit of subsistence, and one bold philosopher has based a theory of the limitation of the number of human beings upon the earth on the insufficiency of the earth to support a greater number. Happily, however, the Malthusian philosophy was promulgated before the days of that great agricultural renaissance which has been brought about chiefly through the efforts of experimental agricultural chemistry. I am not so blinded by the achievements of agricultural chemistry as to deny to many other branches of science an important and, in many cases, necessary influence in this development of agricultural science; but I think every candid man will admit that in this development chemistry has always taken the front rank and led the way. This is preeminently true of the investigations into the nature and extent of the plant food available on the surface of the earth. In this country, owing to the great stores of wealth which the past had accumulated in the soil, it is only within recent years that the question of the supply of plant food has assumed any practical importance. As long as there were virgin fields at the disposal of the agricultural rapist, the conservation and restoration of exhausted fields were of little consequence. The result has been that the wealth of hundreds or, perhaps, thousands of years slowly stored in the soil has been poured forth in a century, not only for the enrichment of this country, but for the benefit of all countries. Unfortunately or fortunately these stores are now practically explored and there is little left in this land of virgin fertility to tempt the farmer to new conquests. Not only have these stores of plant food been utilized but, much to the discredit of the American farmer, they have been wasted. The mark of good agriculture is to see fields yielding annually good returns and increasing or at least not lessening in fertility. This being true, the history of American agriculture to within a few years must be the history of bad farming, for everywhere we have seen fertile fields losing their fertility and farms once productive abandoned. No difference how great the store may be, if it be continually drawn upon and never replenished, the day will some time come when it will be exhausted. This day has come to a large portion of the agricultural lands of this country and to-day there is an awakening everywhere in regard to the best methods of checking the waste and of restoring what has been lost.

I desire for a brief period on this occasion to call the attention of the chemists of this country to some of the methods by which plant food is removed from the fields and some of the direct and indirect ways in which it is and may be returned. On a former occasion[a] I have discussed the extent to which plant food is removed from the soil directly in the crops and the dangers which arise to an agricultural community which continually exports its agricultural products. On that occasion I pointed out the amount of potash, phosphoric acid, and nitrogen per acre annually removed by the crops of the United States, and showed that the only safe agricultural products to send out of a country were sugar, oil, and cotton. It is true that with native, unexhausted soils a country may acquire great wealth by agricultural exports, but the history of the world shows that a country which depends for its wealth and its commerce on agricultural exportation is in the end reduced to pauperism. A single example may serve to accentuate this remark; I refer to the island of Cyprus, which two thousand years ago was the granary of many cities bordering on the Mediterranean Sea. Supplying hundreds of thousands of people with corn, it gradually became impoverished, and to-day its soils are perhaps the poorest of any known.

The waste to which I desire to call your attention to-day is not that which normally takes place in the production of a crop, but that which is incidental to the cultivation of the soil and to a certain extent unavoidable. My purpose is to develop, if it be possible, the relations of agricultural chemistry to this waste, with the purpose of pointing out a course by which it can be returned and in what way we may at least reduce to a minimum the unavoidable removal of valuable plant food. You have all, perhaps, surmised the character of this waste; I refer to the denudation of fields by water and to the removal of soluble plant food by the percolation of water through the soil.

The losses due to the denudation of fields are purely of a mechanical character. The natural forest, or the natural covering of grass over an area of soil, prevents, to a large extent, the denudation due to heavy downpours of rain. The removal of the forest and the destruction of the grass by cultivation leave the soil in a condition in which it is unable to resist the action of flowing surface water. The muddy character of the water in all streams bordering on cultivated hilly fields after a heavy rain storm is a familiar instance of the tremendous energies which are exerted by a heavy downpour of rain in the carrying of the soil into the streams and its transportation toward the sea.

It is not necessary to emphasize the fact that the agricultural chemist is practically powerless to prevent the surface erosion due to heavy rains, but a few practical lessons derived from the application of chemical discoveries to the soils show how, in a certain measure, even surface erosion may be controlled, or at least reduced to a minimum, by the application of the principles of culture founded upon the facts disclosed by advanced science.

The observing agriculturist will have noticed that even in a hilly country a soil in situ underlain by limestone is less likely to be cut up by gullies than a soil similarly situated and deficient in carbonate of lime. The reason of this is plain. In a soil deficient in lime the clays when once brought into suspension by moving water assume a semicolloid state and remain indefinitely in suspension. Clays, on the other hand, which are heavily impregnated with lime salts are in a flocculated state, and the larger aggregates thus produced settle quickly. The result of this is that such a soil is less easily moved by water and a field thus treated less exposed to washing by heavy rains.

The change in the physical condition of the soil which is produced by the lime is also another important factor worthy of consideration. A stiff clay soil is almost impervious to the penetration of surface water, and thus the amount which is carried off is raised to a maximum. A well-limed soil, on the contrary, in which the particles are perfectly flocculated, is much more pervious, and the amount of water which will be retained and delivered gradually to vegetable growth is much greater. Thus the beneficial effects of lime are manifested in both ways—in the better retention of the flocculated clays and in increasing the capacity of the soil for holding a given amount of water in its interstitial spaces.

There are many other salts which also have the same properties as those of lime, but I have spoken of lime salts chiefly because they are cheaper and therefore more economically applied. Perhaps, next to lime, common salt would be the most efficient in producing the results already described; but common salt, being extremely soluble, would soon be leached out of a soil. On the other hand, lime, even when supplied as hydrate, in which case it is somewhat soluble, quickly becomes converted into a carbonate which is practically insoluble in water which does not contain an excess of carbon dioxide.

---

[a] Vice-presidential address before the American Association for the Advancement of Science, Buffalo, 1886.

I am aware of the fact that liming to prevent erosion by surface drainage has not been emphasized as an example of the benefit of the proper chemical treatment of soils, yet I feel sure that all who will give the subject a thoughtful consideration will agree with me in saying that this aspect of the subject is one of no small importance, especially when considered in respect of hilly fields, and even of fields of more level surface.

Without dwelling long upon this point, it is only necessary to call your attention to the immense quantities of soil material annually conveyed to the sea by the causes of erosion already mentioned to show what an active and powerful foe the farmer has in this source of loss. Any one who watches, even for a short time, the volume of water carried by the Mississippi into the Gulf of Mexico will have a most effective object lesson in regard to this source of loss.

A more striking lesson may be seen in the hill regions bordering both banks of the Ohio River. Hundreds of fields once covered with sturdy forests of oak, maple, and walnut, and afterwards bearing large crops of maize, tobacco, and wheat, may now be seen furrowed with gullies, as with the wrinkles of age, and abandoned to brush and briers. The same is doubtless true of other hill regions, but I speak the more advisedly of those which have come under my personal observation.

Great, however, as the mechanical loss of plant food is, it is by no means as dangerous as the loss of the soluble materials caused by the percolation of the water through the soil. The study of the nature of the loss of these soluble materials, together with the estimation of their amount, forms the subject of lysimetry. Agricultural chemists have used many devices for the purpose of determining the character and amount of the natural drainage of soils. Evidently the treatment of a specially prepared portion of soil by any solvent, although giving interesting results, does not indicate the natural course of solution. The only way in which this can be determined is to be able to collect, measure, and study the character of the drainage from a given portion of the arable surface of the earth in situ and under normal conditions. Various methods of lysimetric investigation have been proposed and used, all of them possessing many points of value.

This paper discussed not only the sources of loss of plant foods, but also the methods by which the lost plant food may be recovered and restored. Special chapters are given to the conservation of nitrogen and the increase in its quantity; to the potash deposits and the likelihood of discovering additional deposits to those which are found in Germany; also to the question of phosphoric acid and its increased supply. The progress of the soluble plant foods from the time they are leached from the soil until they are carried into the ocean is traced, and also the methods by which they may be restored to the use of man. The conclusions derived from this study are as follows:

From the foregoing summary of the methods of waste of plant food it has been seen that in spite of all the precautions of the farmer and the chemist, and in spite of the selective absorption of the soil, immense quantities of valuable plant food are carried into the sea, where apparently they are lost to agriculture forever. But this is only an apparent loss. The economies of nature are so happily adjusted as to provide a means of gradually returning in some form or other to the power of the farmer the plant food which has been apparently destroyed. It is true that this return will probably not be to the locality where the waste originally occurred, and it may not take place until after the lapse of thousands of years, but this is of no consequence. Provided arable lands in general receive in some way and at some time a certain return for the plant food removed, it is entirely immaterial whether this be the original plant food removed or other equally as good.

The sea is the great sorting ground into which all this waste material is poured. The roller processes of nature, like the mills of the gods, grind exceedingly slow and small, and the sea becomes the bolting cloth by which the products of milling are separated and sorted out. As soon as this waste material is poured into the sea, the process of sorting at once begins. The carbonate of lime becomes deposited in vast layers, or by organic life is transformed into immense coral formations or into shells. Phosphoric acid is likewise sifted out into phosphatic deposits or passes into the organic life of the sea. Even the potash, soluble as it is, becomes collected into mineral aggregates or passes into animal or vegetable growth. All these valuable materials are thus conserved and put into a shape in which they may be returned sooner or later to the use of man. In the great cosmic economy there is no such thing as escape from usefulness of any valuable material.

In these papers I did not take up the possibilities of increasing the food supply of plants by the action of leguminous crops, nor by the modern method of producing nitric acid directly in merchantable quantities by electrical discharges through confined portions of air; nor did I naturally refer to the vast deposits of phosphates which have been discovered in this country since the date of the papers cited, or to the possibilities of increasing our quantities of potash through the direct utilization of felspar rich in that material. These matters, however, are of such importance in this connection as to merit their extensive consideration.

EARLY STUDIES OF SOIL FERTILITY AND EXHAUSTION.

The exhaustion of the soil, to which reference has already been made, is a fact which was recognized and deplored by the earliest writers on agriculture in the United States. The methods of recuperating exhausted soil were also well understood in the early history of agriculture in this country, due to the fact that the methods used in old agricultural countries were well known by the immigrants. An essay was read before the Philadelphia Society for Promoting Agriculture, on September 28, 1786, by Mr. George Morgan, of Princeton, N. J. This was in competition for one of the prizes offered for the best plan of arranging a farmyard. This essay was devoted largely to the methods of collecting and utilizing the manure. In speaking of the importance of collecting farm manure for its fermentation, he says:

> The earlier it is done the better. But it must be piled so high as that the cattle can not mount on the heaps, and care taken to mix the rich earths, mud, and marl well with the dung and litter. And if, after the first heaps remain a fortnight or a month, they can be turned over, or two heaps be thrown into one to occasion a new fermentation, the dung will be improved. When dung and litter are thrown into heaps without earth, they not only heat, but burn, and thereby suffer great injury in quality and quantity. After the heat has subsided the fermentation is over. If, when heaping your dung, lime can be procured, that is the time to add it in as large a quantity as you can command; but my situation is too remote from limestone to have this benefit.
>
> By the time the whole is thus heaped, that first done will have undergone the proper degree of fermentation for carting out upon your Indian corn, potato, and turnip grounds, which I suppose to have been plowed twice or thrice. My aim is to spread and plow in 40 loads of 20 bushels each per acre; and, with the stock mentioned above, I can manure at this rate from 15 to 20 acres (according to the proportion of rich earths I cart in) every year. My calculation is about 200 loads of marl or rich earth as a foundation for my barnyard. I wish I could make it double that quantity. Gentlemen who have viewed my heaps of dung and my barnyard may form a judgment whether the quantity I mention is exaggerated.
>
> The objections made to my method by common farmers are the expense and trouble of it; yet they allow every load of my manure, without lime, to be worth half a dollar on the spot, whereas it does not cost me one-third of that sum.
>
> The attentive farmer need not be told to dig and wall a receptacle for the juices of his barnyard and to pump them over his dung heaps or carry them onto his grass. He will recollect and practice every means of benefiting his manure. The best method of constructing such a receptacle is particularly described and recommended by the agricultural society at Manchester. As I have not yet built one myself, I beg leave to refer to their directions.

The first premium granted by the society was for this essay, they having adjudged to Mr. George Morgan a gold medal, "The first premium granted by the society, as an evidence of the sense they entertained of the merit of his essay."

One of the earliest experiments in this country in the rotation of crops was that conducted under the auspices of the Philadelphia Society for the Promotion of Agriculture, by a Jersey husbandman, and printed in the Columbian Magazine, April, 1787. The scheme for promoting the increase of crops is as follows:

> I have also laid out a field for a course of crops as practiced in England; it contains 12 acres, laid out, but not fenced off, in 3 acres each. The last harvest it stood in rye, and this autumn it has been plowed deep—some of it trenched. The following course is intended: Lot No. 1, to be manured next spring and sowed with barley; when up, to be sowed with 12 pounds of clover per acre and rolled in. No. 2, oats. Nos. 3 and 4, to be fallowed. The succession will stand as follows:

Year.	No. 1.	No. 2.	No. 3.	No. 4.
1786	Barley	Oats	Fallow	Fallow.
1787	Clover	Barley	Oats	Wheat.
1788	Wheat	Clover	Barley	Oats.
1789	Oats	Wheat	Clover	Barley.

> And thus to continue in a succession of four crops, the stubbles always to be plowed up deep in the fall and laid in three-pace lands, and the barley land to be manured in the fall or spring before plowing and sowed with clover, as above.
>
> It would surprise an European to hear that the average produce of our wheat crops in this neighborhood is under 6 bushels; our farms are laid out in four or five fields, broken up with oats, corn, and a great deal of buckwheat; next year fallowed; third year in winter grain; fourth year in grass, and some also the fifth year. This course leaves little pasture till the stubbles and meadows are opened, by which little manure can be made. No wonder, then, that our crops are light with such constant tillage and scarce any help. The grain has not strength to stand the cold springs; much of it heaves out or is blown away with the March winds.

It is evident from the above that the system of cropping at that period was such as to favor the production of very little manure, and thus to progressively exhaust the soils.

The same author says further on:

> I am also convinced that deep plowing, if not trench plowing, will be advantageous in lands much worn out by tillage without help of manure.

His further advice for improving worn-out soils was:

> Besides breaking up in the fall, deep plowing and drilling, making composts of various materials, and green dressing with buckwheat should not be neglected; also liming where convenient.

In a work entitled "Arator," a series of agricultural essays, written by John Taylor, a citizen of Virginia, in 1813, it is stated, in speaking of the most effectual methods of fertilizing:

> Manures are mineral, vegetable, or atmospherical. Perhaps the two last may be resolvable into one. Mineral manures are local and hard of access. But the earth swims in atmosphere and inhales its refreshments. The vegetable world covers the earth and is the visible agent to which its surface is indebted for fertility. If the vast ocean of atmosphere is the treasury of vegetable food, vegetable manure is obviously inexhaustible.

This early prophecy of the neutralization of the atmosphere as a source of plant food has been verified by the progress of science, which shows that the carbon dioxid with water and the nitrogen of the atmosphere are all abundantly used as sources of plant food. Again the author says:

> It is yet a question whether the earth is enriched by any species of manure except the vegetable or atmospherical; and experiments have hitherto leaned toward the negative. Without new accessions of vegetable matter, successive heavy dressings with lime, gypsum, and even marl have been frequently found to terminate in impoverishment. Hence it is inferred that minerals operate as an excitement only to the manure furnished by the atmosphere. From this fact results the impossibility of renovating an exhausted soil by resorting to fossils, which will expel the poor remnant of life, and, indeed, it is hardly probable that divine wisdom has lodged in the bowels of the earth manure necessary for its surface.

The utility of red clover as a source of securing atmospheric fertilization was also fully recognized:

> To draw from the atmosphere the greatest quantity of manure, to check the loss the earth sustains from evaporation during the process by shade, to give the manure the most lasting form, and to deposit it in the most beneficial manner are primary objects of the inclosing system.
>
> The best agent known to us for effecting the three first is the red clover. Its growth is rapid; its quantity exceeds the product of any other grass: it throws up a succession of stems in the same summer; and these stems are more solid and lasting than those of other grasses. These successive growths constitute so many distinct drafts from the great treasury of atmospherical manure in one year. Whilst these drafts are repeated, the clover is daily securing the treasure, in a form able long to elude the robber evaporation, which it also opposes by shade. To its extracting from the atmosphere the greatest quantity of manure and elaborating it into a lasting form the most suddenly of any other vegetable cover, clover lays for wheat are indebted for their fame. Their success has been attributed to the portion of the vegetable in a succulent state, whilst it was owing to the greater portion which had arrived to maturity previous to the fallow. To ascertain this fact, let one moiety of a clover field be turned in as soon as its first crop flowers, and the other after the stem of the last crop is hard, and the whole sown on one day in wheat.
>
> The peculiar propensity of clover to be improved by a top dressing of the gypsum is another striking circumstance of its affinity to the system for fertilizing land by its own cover. As its growth is suddenly and vastly increased by this top dressing, it furnishes reason to believe that the effect flows from a disposition communicated by the gypsum to the clover for imbibing atmospherical food by its external parts; and so much as it thus gains affords to the earth a double benefit. One, that this food, not being extracted from the stock of atmospherical manure possessed by the earth, does not impoverish it; the other, that being bestowed on the earth from whence it was not taken it adds to its fertility.

In regard to the sources of artificial manure he states as follows:

> The most abundant sources for artificial manure in the most exhausted district of our country are the offal of Indian corn, the straw of small grain, and the dung of animals. We find in the two first proofs of the value of dry vegetables as a manure. If these few means for fertilizing the country were skillfully used, they would of themselves suffice to change its state from sterility to fruitfulness; but they are so egregiously neglected or mismanaged that we hardly reap a tithe of their value.
>
> There is no farinaceous plant which furnishes so rich and so plentiful a crop as the Indian corn. It yields food in abundance for men, beast, and land. By the litter of Indian corn and of small grain, and by penning cattle, managed with only an inferior degree of skill, in union with inclosing, I will venture to affirm that a farm may in ten years be made to double its produce and in twenty to quadruple it; the ratio of its increased value is, of course, still greater.
>
> There is no other secret in the business than that none of these manures be wasted. The agriculturist who expects to reap good crops from neglecting his manures is equally a fanatic with the religionist who expects heaven from neglecting his morals.

In regard to the combination of manures the author says:

> Gypsum, clover, and inclosing, working in conjunction, have within my own knowledge doubled, trebled, and in a very favorable soil quadrupled the value of land in the space of twelve or fifteen years; whilst the land regularly produced two exhaustive crops—those of corn and wheat—in every four years of the period, and these crops were continually increasing.
>
> Of lime and marl we have an abundance, but experience does not entitle me to say anything of either. About a family, a variety of manures may be thrown together and form a small store for gardens and lots. Among these, ashes deserve particular attention. Like other manures, they suffer by exposure and evaporation, but less, because water is a menstruum which will convey much of their salts into the earth if they are spread; the same menstruum conveys most of these salts out of the ashes if they are exposed to it before they are applied as a manure. Hence, when ashes have not been reduced by water in richness they are to be used as a manure more sparingly; and when they have, more copiously. In their unreduced state just from the chimney, when sprinkled an inch thick on the long litter and dung from a recently cleansed stable, they constitute the best manure I have ever tried for asparagus. The beds are well forked up in the fall, covered two or three inches deep with the unrotted stable manure on which the fresh ashes are placed, and so remain until they are thrown into proper order in the spring.

The effect of tobacco on the land is graphically described by the author in the following words:

> Though its profit is small or nothing, its quality of starving everything exceeds that of any other crop. It starves the earth by producing but little litter, and it starves its cultivators by producing nothing to eat. Whatever plenty or splendor it may bestow on its owner, the soil it feeds on must necessarily become cadaverous and its cultivators squalid. Nor can it possibly diffuse over the face of the earth or the faces of its inhabitants the exuberance which flows from fertilization nor the happiness which flows from plenty.

The first account I can find in this country of the use of marl as a fertilizer is in a letter read before the Philadelphia Society for Promoting Agriculture on December 9, 1806. The letter was written by Josiah Reeve, of Rancocas Creek, on the 20th of November, 1806. It is called a "new mineral manure for clover." Mr. Reeve describes the manure as follows:

> The black sulphuric substance by us called marl is found in great abundance through most parts of the country in a northeast and southwest direction from the headwaters of Crosswick's Creek, in Burlington County along on the upper part of nearly all the creeks from thence to the southern part of Gloucester County; we find it in the banks of streams and in most places at the bottom of many of our wells, and it often spoils the water. On my farm and through our neighborhood it abounds near the surface in the meadows and generally in the banks or hillsides, about from 4 to 6 feet below the surface; the depth I can not, from experience, say much about, but from the observations of others find it varies from 6 to 15 feet and more. I have at thy request brought with me to the city for thy use a box of it, of which I wish thee or thy friends to make a chemical analysis. The result of my own and my neighbor's experience is that for grass lands about 10 two-horse loads to the acre—laid on the surface in the autumn—is better, if the next season proves moist, than double the quantity of any other manure and will last longer, changing in two years rough bound meadow into almost clear white and red clover; but the last dry summer it did very little good. I am in the practice of mixing in my barnyard or in the compost heap the marl with the dung, two loads of the former with one of the latter, and always find when put on my fallow that it is as good, or better, than the same quantity of dung alone, and much better for the clover that follows, but in its crude or raw state does not do on grain the first year, except for Indian corn, which some say it helps by laying it on the tops of the hills in the spring. I put some in my manure for my garden and found it made the clover grow among vegetables so spontaneously that we have had much trouble to destroy it ever since.

The above description shows an admirable use of the marl in composting with barnyard manure, and describes the general effects of this marl upon the soil in England, which is easily recognized as descriptive of the same effects to-day. The use of marl or chalk has been practiced from the earliest antiquity in agriculture. In the north of France I saw a number of deep hollows in the otherwise level fields, and was told by the inhabitants that they were ancient marl beds which were used at the time of the occupancy of Gaul by the Romans. The utility of marl in restoring fertility of the soil consists largely in its neutralizing effects produced by the decay of vegetable matter and by its mechanical effects in percolating clay, and thus rendering the soils more porous and spongy. Its efficacy in promoting the growth of clover, as was seen, was known by our farmers more than one hundred years ago.

Another valuable article on the utilization of lime in the improvement of the soil is found in a letter read to the Philadelphia Society for Promoting Agriculture on December 8, 1807. The letter is so interesting that I give it in full:

IMPROVEMENT OF LAND.

CHESTER COUNTY, *November 20, 1807.*

FRIEND VAUGHAN: Agreeably to your request, I now inform you how I have improved my farm. The first three years I could only keep 2 horses and 2 cows, and seldom had more than 4 tons of hay, though the last six years I have grown from 20 to 25 tons a year. Had I taken your advice when I first took the farm, it would have thrown much in my way—that was, to use lime on my land. When I determined to try it, I first got 200 bushels and laid it on 9 acres, planted with Indian corn, and had as great a crop as had been ever seen growing. My neighbors came far and near to see it. The year after, I made a fallow of the land, put in wheat on 3 acres and the rest in rye, and had a good crop. In the spring I sowed it with clover and timothy and put 2 bushels of plaster of Paris on an acre, and had as great a crop of clover as could grow; it laid three weeks before the time of mowing. The lime and plaster did all this, for no land could be poorer before. There are 10 acres in the field, and not being used to spreading lime I laid it on 9 acres; where I laid no lime I got no clover, although I put on the plaster. I have limed all my land and plastered it every year, and never fail of clover. I think 2 bushels of plaster are enough on 1 acre. In one field I have put on 4 bushels on half and 2 on the other half, and I find no difference in the produce. There is another thing in which I was wrong in not taking your advice, viz, not keeping oxen instead of horses. This spring all my horses became sick, and I was forced to buy a pair of oxen. I supposed I should be tired of them, but, on the contrary, I am tired of horses, as I find that with my 2 oxen I can do more work than I could with 4 horses, and with half the expense. I have worked horses for forty years, and if I had used oxen in their place they would have put £500 in my pocket. My oxen go to the limekiln once a week—21 miles—in the morning, and return the next day, in the afternoon; after resting two hours they go to work; horses can not do this. There is another thing I find advantage in. I cut all my cornstalks and carry them to the barnyard for litter; when well trodden I cover them with lime and then add another layer, then more lime, and so on until all the stalks are used. In the spring the stalks are all rotted, and I have no trouble in turning them up. Last spring I had 176 loads of dung. The first three years if I had 20 or 25 loads it was a great thing. My neighbors thought me crazy to buy lime and to be at such expense, but now they are all falling into the same way.

I plow all my land in the autumn for corn, and in the spring lay on the lime, plow it all over, harrow it down, and never am troubled with cutworms or weeds. I find the fall plowing is a great advantage.

Your affectionate friend,

(Signed) WILLIAM ASHFORD.

JOHN VAUGHAN,
Member Agric. Soc. Philad.

The secretary of the society adds some important comments on the letter, stating, among other things, that it is published "for the encouragement of those who live on worn and exhausted lands." Some of these claimed that they could not procure manure, that plaster was not sufficient, and that lime was expensive. An important point, however, is emphasized, viz, "that the mixing of lime while the vegetable substances are putrefying is a mistake. It had better be put on the land, or if it must be mingled with the manure, let it be after the fermentation is over." This is in exact harmony with the present understanding of the fact that lime frees ammonia and thus produces a loss of valuable nitrogen.

The advice given by the Philadelphia Society for Promoting Agriculture to farmers of worn-out land is so interesting that I give it in full:

1. If no water be in your barnyard, dig a well; and confine your stock from November to May, never permitting them to wander after water, or the provender of the stalk field, in which they empty themselves and scatter their dung, instead of filling themselves, either for profit or economy. Let not a hoof unnecessarily leave your yard.

2. Haul into the yard every putrescible substance you can get, and when proper, clean up the yard, and have a pen for your manure, both from the yard and stables, inaccessible to cattle or horses, whose poaching or treading prevents fermentation and is highly injurious. Mix earth with your litter, rather than lime.

3. Plow your fields in the fall 7 inches deep, but plow no more than you can manure, and let the rest lie waste till you can do it justice. Buy lime; if you can not reach 2 acres be content with 1. Move your fences and plow up their sites. Mix leaves, weeds, and all putrefiable substances in long and low beds, so as to be turned by the plow and become excellent compost. For this purpose also go into your woods and with leaves and wood soil make beds of compost of these materials, as well as of the mold in low places into which it has washed or has been deposited by ponds of water or rains and floods.

4. Lime your fall-plowed fallow with 40 bushels to the acre. Plant Indian corn; put compost on the hills and plaster the corn.

5. After the corn is gathered cut your stalks and haul them to your yard. Plow again for a winter fallow. Your plowing (except for seed) should never be less than 5 to 7 inches deep.

6. In the spring harrow in buckwheat, to be rolled and plowed in when in full blossom with an East Jersey plow without a coulter, or any other that will not choke.

7. Put on what dung you have made and plow it in with your seed. Your compost will now be fit for top dressing your wheat, which is to be the crop of this year; and sow no more than you can manure.

8. On the wheat sow clover seed, and the succeeding spring plaster the clover. All this can be accomplished in two or three years. When you have perfectly learned this alphabet you will get into habits that will enable you to teach instead of requiring instruction.

9. When your old fields have inert vegetable matter (as is the case with most old fields) plaster them to throw up pasture, and increase your stock by this additional subsistence.

10. Never sow in a foul or weedy fallow to save a plowing, or on a wet one to save time. Avoid oats and exhausting crops and never stubble in or let one chaffy-husked or culmiferous crop immediately follow another.

11. Change your crops and destroy weeds, or they will destroy you; turn a foe into a friend by turning them into manure. Explore your own and the neighboring farms for marl, clay, peat, earths, or substances for experiments on your fields. Be not discouraged by failure, but persist in essays on a small scale till you succeed.

The use of lime and its value in preserving and increasing fertility is further illustrated in an article in the Annals of Agriculture and Other Useful Arts, published by Arthur Young, London, volume 2,

1784. This is found in an account of a fortnight's tour in Kent and Essex, page 39:

The circumstance in their husbandry most deserving attention is the use of chalk as a manure. They bring it all from Malden, at the distance of 6 miles; it is brought by sea from Kent, and a wagonload costs at the quay 10s. The method employed is this: The teams of five horses and a wagon and two men go out about 12 at night, load at Malden, return, unload, bait, go again with the same wagon and horses and return and unload and all over by 1 o'clock at noon. This is, I think, the severest work I ever heard of; 24 miles with so heavy a load, twice to be loaded and twice unloaded by the same men, yet it is here common; they reckon that every load costs in the whole 20s. They lay from five to eight on an acre, either upon a clover lay while feeding, or on a summer fallow; the effect exceeds anything I have met with; a very thin dressing of it is seen immediately to an inch, like rotten dung, and lasts twenty years; fifteen in great heart. Mr. Cott showed me from his garden a field of wheat hanging on the side of a hill at the distance of half a mile, one part of which was evidently much inferior to the rest which was in general laid; that part was the only spot not chalked, the farmer not having time to finish the field; he was present and confirmed the account. The same farmer (Mr. Parkinson, of Brackstead) having chalked a field, brought some in a cart as they returned from the field, and spread it thinly on one spot in a piece of poor, dry land; the whole was sown with turnips; during the whole season from their coming up that spot was to be seen at a great distance, and the roots were far larger than anywhere else.

They think their lands will do nothing without chalk, insomuch that the whole country will, in a few years, have all been chalked. The soil on which it does such wonders is loam; they have very little clay and no sand. On gravels the effect is but slight; it is the good sound loam in which it answers like the richest dung.

It is a general opinion among them that land which has once been chalked will not take it again, and this opinion seems to prevent the trial; they acknowledge, however, that mixed with earth and dung it is even then excellent. A very particular circumstance they have observed is that laying a slight dressing of chalk and earth or dung on a field never chalked will take so much effect that the same field will not then answer to chalk completely. Another remark they have also made is that the chalk presently gives the land a red color; so that a part of a fallow that has been chalked will, from the tinge, be discernible at a distance.

Upon my asking Mr. Parkinson if they ever laid chalk upon meadows, he replied they did not require it, besides, they supposed it would do harm as they observe that it is a strong enemy to grazing; that is, to the ground covering itself with good grass. A field which before chalking will run of itself to a fine head of white clover no longer does it after chalking; this is very remarkable, for one would suppose what is manure for corn would be so to grass.

The chalk is not soft, but rather hard; the sharpest frosts leave very many lumps unbroken, so that they break them with pickaxes; and the hard bits that break to a clear white they say come from the bottom of the pit and are esteemed better than the pieces which crumble between the fingers. I tried some pieces at Mr. Cott's in vinegar and water; the effervescence with the former is pretty considerable, though not near equal to what I have seen; but in water it falls very slowly, if at all.

Some farmers have tried lime, and with great success, upon the soils proper for chalk; this is a fresh instance that the excellence of these manures much depends on the soil whereon they are laid; on good loams they take full effect, but on poor lands they find nothing to work on. About Ensield the same chalk does wonders, which at North Mims has very little effect; the one is a rich loam, the other a poor gravel.

An interesting account of air as a plant food is found in the Annals of Agriculture and Other Useful Arts, published by Arthur Young, London, 1786, volume 1. In this volume, on page 169 and following, is an account of some attempts to apply air as a manure to the soil:

The theory which our great philosopher started, that phlogiston is the food of plants, appeared to me so important in the philosophy of agriculture that it engaged my earnest attention. It has never been my conduct to abandon to speculation that which can be brought to the test of experiment. But a person in such retirement as I live in, without opportunity of communicating with practical chemists and philosophers, with smaller means of overcoming difficulties by force of large expenses, and without experience in the sciences necessary to pursue such inquiries, far from all other assistance; a person thus situated may feel very earnest desires to pursue a line of activity and vigor, and yet experience the mortifying conviction that, for want of better support, his wishes may be in vain and his efforts useless. Many of these feelings have been mine through this little beginning of my inquiries; imagining a multiplicity of experiments which I had not the power to execute.

Being desirous of knowing what were the discoveries on which this theory was founded, I read the five volumes of Doctor Priestley with attention, and also Doctor Ingenhouz's experiments on vegetation; and I was exceedingly surprised to find that, amidst a great career of experiments that may indeed be called a new world for the ingenuity of mankind to range in, though the trials were numerous and decisive which prove the power of plants to imbibe phlogiston from impure atmospheric air, yet those which show it to be taken in as a pabulum or food are very rare. Even in the most remarkable of Doctor Priestley's, the willow plant thriving best in inflammable air, an instance is given in the same page of mint thriving much worse in it than in common air. And in a letter which I had the honor of receiving from him upon this subject, July 1, 1782, he expresses himself thus: "Though I have no doubt but that phlogiston is the essence, as we may say, of the food both of plants and animals, they are not capable of extracting it except from certain substances and in certain circumstances; and phlogiston administered in any other way infallibly kills both." The doctor means, I apprehend from other expressions in his correspondence, that the phlogiston must be given either as the result of putrefaction applied to the roots, or else in air applied to the leaves, in which I entirely agree with him. The labors of that truly great man are almost universal; a reach of sagacity, a depth of penetration, united with an ardor, and even enthusiasm, in pushing his researches with an unremitting industry that removes difficulties in the very moment of discovering them, would have left us nothing to wish in the present inquiry had it been possible for one mind to bring to maturity the ideas he has thrown out for the employment of thousands. The variety of his pursuits has prevented so marked an application of his discoveries to my favorite art as might otherwise have happily advanced it.

If there are any experiments extant in which the express application of phlogiston, or of inflammable air, to the roots of plants as a manure has been made I am ignorant of them. No such application, or even conjecture of the result, appears in any work that I have consulted; and yet it seemed to be the only method by which the question of that substance being the food of plants could possibly be decided. The effect of it on leaves, from the experiment of Doctor Igenhouz, seems rather to be an edulcoration of impure air for the purpose of making it salutary to the human body than necessarily beneficial to the growth of the plant. If this is not the exact result, I may at least observe that the doubt which arises might be very easily resolved by those who have the skill and apparatus necessary for such experiments.

The leaves of a plant may perform the office of lungs in the body of an animal, and inflammable air may be as salutary to their inhalation as dephlogisticated air is in the respiration of animals; but it no more follows (however likely it may otherwise be) that phlogiston is therefore their food than that pure air is the food of man.

Following this are records of a number of experiments, and the conclusions are given on page 184 and following:

Many of the preceding experiments may, perhaps, be found to open the way toward a more consistent theory of vegetation than has yet been established. Had not inflammable air been tried the leading feature for selection would have been the effect of the volatile alkali, which is uniformly excellent and, as putrefaction is known in common practice to yield admirable manure, it might have been concluded, with great propriety, that the volatile alkali was the food of plants, a theory for several years the favorite deduction of my practice. But inflammable air having so decisive an effect, analyses, if I may use the expression, of that alkali show us to which of its parts we are to attribute the result, viz, phlogiston in a volatile state.

The volatility of the element seems essential to its action on vegetation for, in a fixed state, it appears to be attended with little or no effect, and in most cases with a mischievous one; for, though charcoal operates considerably as a manure, yet the white ashes of that body being almost uniformly superior to it will not permit us to attribute the effect to its phlogiston. We are rather to suppose that it operates mechanically in the manner of wood ashes. Pitch, tallow, red lead, sugar, and powdered flint are poisons; these substances abound greatly with phlogiston, but not in a volatile state. It is very remarkable that in the form of a liquid it is mischievous unless in the volatile alkali; not only in spirits of wine, but in that most volatile liquid of all others, ether. Oil of every kind the same, and in general let it be mixed with what it may; a circumstance the more remarkable, as a very ingenuous physician (Doctor Hunter, of New York), for whom no one has a greater respect than myself, actually fixed an oil rendered miscible with water as the food of plants. Keep that mixture, or any other substance in nature capable of putrefaction, till it is putrescent, and I have no doubt but you have the food of plants. Why? Because you then have phlogiston in a volatile state.

Still, however, spirit of wine being so prejudicial, surprised me a good deal till I found it was generally considered as composed of an acid united with phlogiston. All the three mineral acids are uniformly poisonous to vegetation; the acid is, therefore, prevalent enough in the spirit of wine to act in its usual manner. Sulphur also has always been a poison, though in some instances it has seemed to act for a short time as a stimulus. Fixed air proving in any case beneficial surprised me, for if the food of plants depends on the volatility of phlogiston the result of putrefaction (which is the fact in nineteen instances out of twenty) then every antiseptic ought to be pernicious (not to mention the proof Mr. Bewley gives of its being an acid). We must, however, remember that the benefit of it in the preceding trials is by no means so well ascertained as that of inflammable air.

To discover facts hitherto unknown in science can hardly fail of being useful in the end, however deficient in that respect they may appear at first. The inquiry is worth the pursuit, though not immediately applicable to the practice of any art. But, in the present case, we can scarcely take a step that is not nearly connected with common agriculture. If phlogiston in a volatile state be the food of plants the farmer has a lesson of infinite importance to him; to acquire and cherish as much as possible the effects of putrefaction and consequently to manage his dunghills and other receptacles of manure in such a manner as to prevent the escape of the volatile principle generated by the putrescence. In this view the practice of frequently turning dung over, which is reckoned by some writers so very excellent, will, perhaps, be found after one stirring uniformly pernicious and tending only to let loose and dissipate in the atmosphere the essence which would most contribute to the fertility of the fields. Without a certain degree of putrefaction the phlogiston will not be volatile; continued too long it will all fly off. Consistent with this theory is an observation I make every year in my own farmyard. I have a standing sheepfold, part covered and closed and part of it uncovered; the whole is littered equally, but one load of the dung in the covered part is worth two in the uncovered. When the carts go in to be loaded it stinks much more offensively and makes the men's eyes water that move it. This shows that the volatile alkali and phlogiston are retained and that the action of the sun and atmosphere is to carry them off.

I wish much to have made some progress in deciding the effect of sunshine on soils, but, except the experiments on earth kept seven years excluded from both light and sunshine and also kept in a vault, I have not been able yet to execute the trials I have projected, though some of them are at present in course. Those were decidedly against the soil imbibing any food from the action of that luminary, and the whole range of common husbandry seems to speak the same language. Covering the soil with a thick, smothering crop of clover, tares, pease, etc., is found to enrich it far more than a summer fallow. Old meadow land receives very little of the sun's rays, and some woodlands none, yet these are the richest soils all over the world, because the putrescence of vegetable and animal matter impregnates them with volatile phlogiston. I can not conclude these experiments without admitting an imperfection for want of more spirited and extensive trials (many of which I had planned), but the expenses necessary are beyond my ability, and no day passes without my regretting that insufficiency for pursuing the hints that arise. Time is precious.

> Life flies fast away, and leaves one little more than wishes to execute what fortune forbids. I should be glad to try electricity by means of a machine constantly turning by wind or some other power. I want a very lofty conductor to bring down the electric fluid from the clouds, to impregnate certain recipient bodies, with and without plants growing in them. I wish—but wishes are vain and unworthy every philosopher; experiment is his business; we must content ourselves with doing the little in our power.

The question of lime was again considered in a communication read by John Lang to the Philadelphia Society for Promoting Agriculture, on August 9, 1808, and published in the second volume of the Memoirs, page 1 and following:

> We have for some time past heard much talk about two varieties of lime, the one useful or favorable to the growth of vegetables, when used as a manure; the other hurtful or pernicious, and therefore not to be used for that purpose; the first is termed calcareous, the other magnesian lime.
>
> The first notice we have of this magnesian lime is from a communication of Mr. Tennant, published in the London Philosophical Transactions.
>
> This is doubtless a subject of great importance to farmers and, in my opinion, deserves to be more fully investigated. If all lime which contains magnesia is only useless as a manure, it must be of great importance to our farmers to be informed how they may be able to distinguish this from the calcareous lime; but much more so if it is, as Mr. Tennant says, destructive to vegetation, and that it diminishes the fertility of the soil. The distinguishing characteristics of these two varieties of lime mentioned by Mr. Tennant, it would seem, can only be discovered either by analyzing (which process farmers are generally ignorant of) or by making experiments by applying it to the soil. It is said that magnesian lime when used in too great quantities renders the soil less fertile, and wherever a heap of it has been left on one spot vegetation will be prevented for many years; while of the other sort of lime, a large quantity is never to be found injurious, and that the spots which are entirely covered with it become remarkably fertile instead of being rendered barren.
>
> From the above statement it would appear that by far the greatest proportion of all the limes used either in this country or in Europe are of the magnesian kind, or in other words must contain a certain proportion of magnesia. For my own part, I have never seen pure calcareous lime, unless that made from calcined shells may be denominated such; though I must own I am not chemist enough to be able to discover the magnesian lime, except by its effects upon the soil, as above described by Mr. Tennant and Doctor Darwin. The distinctions which some farmers make of hot and mild lime, Mr. Tennant believes to mean magnesian and calcareous lime. And the Doctor says he is informed that the magnesian lime is preferred in architecture, and is said to go further in making mortar, etc. If this is the case I think it will be admitted that all the lime used in the United States, either for building or manure, is of the hot or magnesian kind; as it is well known that the lime of this country is generally stronger and of course will go further in making mortar, or as a manure for land than English lime. Were our farmers in this country to discover lime of so mild a quality that thistles and grass would grow up through the sides of the heaps of it, but at the same time it would require three loads of this lime to produce the same effects upon their land as two loads of the lime now in use, I think they would surely prefer the latter to the former. Our farmers know very well that wherever they lay their lime heaps every particle of grass or other vegetables will be destroyed; and that the spots on which it lay will not bear any crop for a year or two after, unless they are careful to remove it so clean that no more shall remain on these spots than the same proportion which they spread over the rest of the field. They likewise know that if they should leave their lime heaps exposed to the influence of the atmosphere, to successive frosts and thaws, rains and snows, etc., it would in time become as mild as the calcareous lime destroyed by Mr. Tennant. But then it would be useless for mortar, and for land it would be like some medicines of which the chief recommendation is that if they do no good they will at least do no harm; and for that reason they commonly cover the heaps over with sods, or straw, etc., till the land is prepared for putting it on. Our farmers likewise know that poor land will not bear so much lime as rich land, and that if they should by mistake over-lime their land, the succeeding crops will rather be hurt than benefited by it; and in such cases there is no remedy but either to

give the field a dressing with dung or let it lay a year or two till the heat of the lime is partly given out, and then it will have its effect. From this I conclude that lime must act as a stimulant, and that the quantity applied to the land ought to bear an exact proportion to the carbonic, or vegetable matters contained in the soil. It is well known that stimulants used in small quantities are in some cases very useful in the animal economy, but in great quantities they will destroy animal life.

I would not by any means presume to call in question the results of Mr. Tennant's or Doctor Black's experiments; on the contrary, I am rather inclined to believe that all stone lime contains a greater or lesser proportion of magnesia; but that the lime which contains the greatest proportion of that earth is totally unfit to be used on land as a manure, I think deserves a second consideration.

Doctor Darwin observes that the substance called chalkstone is almost wholly magnesia; now I know from experience that chalkstone land is the most kindly to all sorts of grain of any soil I am acquainted with, and will bear a longer succession of severe cropping before it is exhausted. But perhaps it is the process of calcination which gives to the magnesia that caustic quality which renders it so hurtful to vegetation, as Mr. Tennant found by his experiments, that 30 or 40 grains of lime did not retard the growth of seeds, more than 3 or 4 of calcined magnesia. From which Doctor Darwin concludes that, as both injure vegetation in large quantities, they may both assist vegetation in small ones.

Consistent with the doctor's remark I would just observe that there are many substances which make rich manures when used in small quantities; for instance, I have seen very great crops of barley got by sowing the land with pigeon's dung, as thin as we sow rye, and harrowing it in along with the seed barley; whereas had it been put upon the land as thick, or half as thick, as we would put stable or barnyard dung, it would as effectually destroy all vegetation as hot lime used to excess. The same remarks will apply to the dung of all kinds of domestic fowls, also to human dung and urine, so much valued in China. Common salt has often been recommended as a great assistant to the growth of vegetables when used in small quantities, whereas it is well known that the excessive use of it will render land totally barren.

It will be admitted on all hands that all animal and vegetable matters contained in the soil must undergo a decomposition by some means or other, so that being thereby reduced to such a state as to be easily soluble in water, they may be readily absorbed by the tender roots, by some termed the mouths of plants. That the roots of plants naturally possess to a considerable degree the power of producing this decomposition, I have had occasion more than once to observe, in the case of planting potatoes with woolen rags instead of dung. I have seen fine crops of potatoes raised by dropping a small piece of woolen rag, not larger than the hand, in the furrow along with every set of the potatoes when planted, and I have observed when the potatoes were gathered in the fall that, in every instance where a potato plant had failed to vegetate, the rag was turned up entire, very little damaged by being buried under ground; whereas, on the other hand, not the smallest vestige of the rags were to be seen in any part of the ground where the plants had succeeded and grown to perfection. Only I observed in some instances where the rag had been uncommonly large, a white moldiness upon the soil about the roots of such plants, which seemed to me an indication that more nutritious matter had been formed than could be absorbed by the roots. Besides I observed the palms or tops of such plants were always large and of luxurious growth, while the potatoes at the root were small and not fully ripe.

But there are other animal and vegetable substances which require more powerful solvents to prepare them for the food of plants; such substances must be decomposed either by means of the putrid fermentation, or by the application of hot lime, etc. But while the putrid fermentation is going on, it is exceedingly noxious to vegetation, as we may see by the bad effects of putrid or stagnant water upon the roots of tender plants; while on the other hand, hot lime will check the progress of putrefaction, and at the same time very quickly effect the decomposition of various bodies; thereby preparing sweet and wholesome juices, whether they consist of carbon, phosphorus, oils, or alkali, or compounds of all or either of these. And I conceive if the lime meet with a sufficient quantity of such substances as it in this manner acts upon, it will, by mixing with such juices, thus prepared, be thereby deprived of its caustic quality in the same or somewhat similar manner to that whereby magnesia or chalk blunts, or sheaths, the points of the sharp particles of acids. But if the lime does not meet with a sufficient quantity of carbonic or other matters in the soil to act upon, so that its caustic quality may be completely overcome, then in such case it will act upon the tender roots of the growing plants, in the same manner as it acts upon grass or other vegetables when laid in heaps on the surface. And this is in my opinion the cause why lime in some instances is hurtful, instead of being beneficial to land.

Upon the whole, I think instead of troubling our farmers about distinguishing the different qualities of magnesian and calcareous lime, it will be better to advise them to use lime sparingly on poor land, and at the same time to use every exertion to increase their dung and compost heaps, whereby their land will be prepared for the application of lime, not only with safety, but great advantage.

An interesting article on the improvement of soils is found on page 187 of the Memoirs of the Philadelphia Society for Promoting Agriculture, volume 2. The communication bears date of March 9, 1810:

It is generally acknowledged that the best land may be reduced to sterility from an injudicious rotation of crops. It remains in a great measure to be proved, whether a farm, which from bad management had been rendered barren, can be restored to its pristine fertility, by a treatment, not beyond the reach of every farmer (nor without the farm) who possesses the land, free from incumbrances, which are nearly equal to the supposed value of his worn-out farm.

When an inquirer examines the publications of those who have given the results of their experiments, it appears not only practicable, but easy; frequently, however, some circumstance is not mentioned in the communication or something not attended to by the reader who intends to make the same successful experiments, but fails, from the causes stated.

The Rockland farm exhibited a subject for experiment, as it had not only been reduced by cropping, but generally, became a common for every animal to take what remained of the scanty natural, but coarse, herbage; having read in various books the results of sowing plaister and clover, it was presumed that sowing plaister and clover would be the extent of the expenses required to fertilize the fields in a few years; a few experiments proved that the plaister and clover seed were both lost, as no one could at any season of the year point out what field or upon what part of any field they had been deposited, unless where the briars and bushes had been eradicated.

It should, however, have been mentioned that the soil was generally a cold or heavy clay, some blue, white, light brown, and a few spots of red clay, loaded with hard blue stone and rocks, chiefly quartz, mixed with iron and copper. Some of the experiments were made with plaister, others were made by top dressing with lime, at the rate of 25 to 30 bushels per acre; the lime was brought 20 or 25 miles from the kiln, and laid on the field at 25 cents per bushel; it was formed into a bed of about half a foot thick and covered with earth, plowed and thrown over it, before it was slacked, that all the phosphoric principle disengaged by the water might be united with the earth which covered it; a heavy harrow was afterwards passed over it, so soon as the shell was reduced to powder; the bed of lime and earth was then frequently turned by the plow and harrow until the whole assumed the appearance and smell of soapers' ashes, containing about 10 parts of common soil to 1 of lime. It was then carted and spread regularly over the field, and in every instance it gave a return of clover equal to 10 loads of stable manure to the acre. The idea of mixing the lime and earth was suggested from spreading the refuse mortar of lime and sand gathered from about buildings and laid upon the field, the effect of which I observed was more immediate than any equal quantity of lime; though mixtures of lime and earth were equally so, in both cases the lime was completely pulverized, and the sand and earth broke up the communication of lime with lime, and the succeeding rains carried the fertilizing principle of the lime, as from a sieve, into the soil where it was spread; it completely divided the soil, rendering that open and warm, which before was compact and too cold for the roots of the grain to live in.

The whole soil, which before felt dead under foot, became so elastic that persons of observation, by walking over the field in the night, distinctly told how far the lime and earth compost extended. The color of the soil was likewise changed into that of chocolate.

These effects presented several ideas which had not occurred to me before, viz: That anything which would separate the particles of the soil and admit the air would render these cold and heavy clays warm and fertile; that the free intercourse of air would carry off the acid. To meet this, plowing in the fall was adopted and found successful. One-half of a field six years ago was plowed in the winter, the other half plowed in the spring. That part which was plowed in the spring has never brought grain or grass equal to the other. It should have been observed that the field had not been plowed for upward of twenty years, and of course a great body of rubbish and roots were plowed in after the briar hook and grubbing hoe had smoothed the surface. Spreading of manure in the autumn from the compost bed has also been introduced with universal success, both upon grain and grass fields, the lye or salts of the manure being carried into the soil by the rains upon the breaking up of the frosts, which have in some measure prepared the soil to receive it. High agricultural authorities, even bottomed on accurate observation, are opposed to the practice of spreading out manure in autumn. Amongst these we find the justly celebrated Lord Kaims, in his Gentleman Farmer, a work upon first principles, and deservedly of the highest authority. A departure from his judgment is only to be allowed where facts would censure silence; nor should his name have been mentioned unless to avoid the charge of writing without attending to what has been said on that subject. It is no conclusive objection that "the strength of the manures will be carried off by winter rains or exhausted by the frost." Are not the warm showers more so, and are not the exhalations more copious in a warm than in a cold temperature? Is the descending of the sap in trees no monitor as to the season for spreading out manures, and about the operation of nature for renewing and invigorating the process of vegetation?

Briar bushes and all vegetable substances have been covered up with earth, rotted, and used with the same success as stable manure, and so far and so long as they separate parts of the soil and admit the air they fertilize and change the color of the mold. These experiments, tested by frequent repetition, have laid a foundation for experiments less expensive and equally fertilizing for the production of grass and grain. Plowing and sowing for the purpose of producing pasture and accumulation of vegetable soil have been adopted. For this purpose wheat, rye, Indian corn (maize), buckwheat, and oats have been sown upon fields plowed, which were incapable of producing any crop. None of those grains have produced pasture and vegetable soil equally valuable to that from the oats. Where the others have failed its roots have pierced, disarmed, and vanquished the inhospitable soil and rendered it fertile. The winter plowing is continued and the oats are thrown in as early as the season will allow, sometimes even in February, either upon what has been plowed in autumn or in the fields which were in corn the preceding year or in pasture oats the preceding fall. In general they afford early pasture, and when they are replowed in July and August and sown again with oats they furnish excellent pasture from early in September until late in December, during that season when all other pasture is generally dried up. The first sowing of oats only gives about two months' pasture, but the roots and remaining herbage afford a manure for the second sowing, and this always yields four months' valuable pasture, which no other course known to me will afford. In September, October, November, and December considerable attention is required to preserve the young clover which the field will be able to raise in the second year of the oat pasture. If sown with the oats in the spring, the cattle should never be put in while the ground is too moist, as they would destroy and tread it into the soil; and sometimes dry seasons are also highly injurious to the clover. When the clover is sown with the second sowing of oats the same care is required to prevent its being trodden in by the live stock. For this purpose it is always necessary to have a spare field of old pasture, which they will feed upon in wet weather and which they would not relish in dry weather. To guard against a dry season it is most proper never to pasture the oats where the clover is sown so much as to prevent the herbage of the oats from giving shade to the clover. So soon as a field will produce clover luxuriantly, there is no farmer at a loss how to make his field as rich as he pleases, and having got them into good heart, it will be to his interest to put them in such rotation as shall increase the vegetable soil and consequent fertility of his fields.

It is almost unnecessary to mention what will make its way to the understanding of every farmer, viz, the many advantages gained from treating his barren field in this way.

1. Early and late sweet pasture from such fields which otherwise produced a scanty, coarse herbage unpalatable to every animal.

2. Immediate reward for his labor; the stock are supported by it within two months from the time seed is sown; the two returns give six months' green food; he is not, however, to depend upon it for all his summer pasture.

3. Perhaps it is one of the most effectual means to root out garlic, because what have escaped the plow in the spring are eaten down with the pasture from the first sowing of oats and prevented from going into seed; the plowing in July and August expose so many of its bulbs to the sun that few shoots are to be found in oats sown for fall pasture.

4. It is an easy and profitable way of clearing grain fields from every species of injurious weeds, as it will convert them into vegetable soil and enable the farmer to raise whatever grain or grass he shall judge most suitable to the soil.

5. It will save the expense of a fruitless summer fallow, and the green herbage will aid the dairy.

6. It enriches the farm from within itself, and no expense is required beyond the reach of any farmer; by rising one hour earlier, and working one hour later than usual, for two weeks, he may plow and sow 2 acres, as an experiment. The pasture will recompense his labor, while his soil is greatly improved; it is equally evident that the fertility of the soil is acquired partly from the roots of the oats opening the soil and introducing the air and warmth of the sun and partly from accession of vegetable soil produced from the decomposed roots of such pasturage; but even before the roots are converted into soil they produce the most beneficial effects. Those from the spring sowing retain the moisture and supply the summer sowing with it. The roots from the fall pasturage, being full of sap, introduce winter frosts everywhere into the soil, which, swelling with the congealation, separates the particles; for it is to be observed that roots, while the stem is eaten down by the stalk, do not become hard, but are more numerous than when the plant is matured into grain. It is however necessary to sow at least double the quantity of seed to that required for crops of grain, the pasture being so much the thicker and the increase of vegetable soil from the decayed roots so much the greater.

It is not to be expected that one or two repetitions of the series of oat pasture will make the soil equally rich as a common dressing of stable manure, which from a farm of 100 acres will not in general extend over more than 10 or 15 acres; this gives to one acre nearly the vegetable soil produced from 7 or 10 acres. It is to be remembered that the object proposed was to render worn-out or barren fields productive; and in no case have I found a field which was not after two years, oat pasture capable of producing clover and receiving the gypsum with evident advantage. So soon as a field produces clover no one is at a loss how to produce advantageous crops afterwards. It is in every one's power to estimate what the plowing and seeding per acre of oat pasture with cost, and, according to circumstances, so will the expenses be, but in general where the expenses are high, the value of the pasture is equally so, and if even granted that the cost of plowing and seeding shall be double in value to the pasture produced let the comparative value of the field be fairly estimated before the course was begun—a waste or worn-out field—and what it is now, when the course is completed and laid down in clover, timothy, or orchard grass.

It will be of the first importance to have at least two fields, otherwise if the cattle are constantly upon the same field it will not be found so productive, and in wet weather they should be turned into some field where the herbage was too hard in dry weather. It will be eaten greedily by the cattle after they have been satiated with the soft blades of the oats; under this management, beeves have been fatted for family use and taken off in December without any grain. It is observed that the oats scour at first, but the free use of salt readily corrects the complaint, and in no pasture do they rise faster in flesh, and the juices of their meat are uncommonly grateful.

The fields which have been in corn the preceding year have also been sown in the spring without being replowed, and have done equally well, except upon heavy clays, when the spring has commenced with heavy rains which have rendered the soil too compact to be opened, even with a heavy brake harrow, drawn by four-horses. The fields from the oat pasture the foregoing autumn have also been sown without replowing, when the spring has set in without much rain, after severe frost; not only the oat pasture but also the clover sown therewith have answered well.

Oats have also been sown among the hills and drills of corn after it has received the last dressing. It has succeeded, without any visible injury to the corn, provided care has been taken not to injure the roots by the plow or harrow at the time the oats were sown.

It has been inquired, Are not all crops of oats exhausting? If so, how can two sowings of oats in the same year render the soil fertile? It is granted if oats shall be matured into seed they will certainly exhaust, but if cut off while in the blade they and all culmiferous plants will fertilize. The experiment was made with Indian corn, sown broadcast, cut twice, and carried to the stable, and a crop of turnips taken off the ground the same season; the manure was laid on before the corn was sown, but none was given when the turnip seed was put in.

Another way in which oats fertilize appears to be from increase of vegetable soil. This is within the view of every observer. The remains of the pasture plowed in, particularly in July and August, is speedily decomposed, its tenderness and moisture aiding the dissolution. But dry stubble and husky roots are difficultly decomposed, nor do they produce so much carbonic or coally matter in the soil, which chemists say decomposes the water and produces the air required to promote vegetation. As the vegetable is produced from air and water, and not from earth, which seems to be no more than the laboratory where the process of vegetation commences, and finally serves as a matrix to hold one part of the plant while the other parts are raised aloft in quest of superior aid to complete the inscrutable operations of the vegetable fabric.

It has also been inquired, Will this process of oat pasture fertilize everywhere? It is answered that where the soil and climate are the same the effects will be the same also. A description has been given of the soils where the experiments were made and are still going on. If experiments of the same nature shall be made upon a different soil and climate the result will be different, and more or less favorable, according to circumstances, and for which the practice now mentioned can not in justice be rendered accountable. If my shoe fits my foot I am warranted to say it will suit a foot of the same size and shape everywhere; let no one conclude that it will fit a foot of larger or less size or different form; but I must confess that passing over things equally obvious I have run into numerous and expensive errors.

But when it is inquired upon what evidence it is to be received, the reply is at hand; living evidences are at the command of everyone who chooses to make the trial; let him, however, be on his guard against suffering himself to take a crop in place of the spring pasture oats.

If it shall still be inquired, How does the oat pasture fertilize? it may be also observed that the constant verdure and green herbage prevent the rays of the sun from parching the soil and depriving it of its moisture and air, both of which are highly necessary to vegetation. The double portion of juicy vegetable matter arising from the two crops of pasture in the same summer being everywhere united with the common soil, partly mechanically and partly chemically, renders the soil capable of retaining sufficient moisture and elastic air to make it open and warm, and by which the soil does not only become thicker by going downward, but actually expands or rises so as to give a furrow, considerably deeper than formerly, over immovable rocks. Some years ago a field in view of the farmhouse marked the broad rocks during the course of every crop; they are now covered with so much soil that they are seldom observed. The two plowings also contribute to the increase of the air in the soil, without which no soil can be fruitful, there being no vegetation in vacuo. Tull's horse-hoeing husbandry was introduced under the idea that the pabulum of plants was pulverized earth. The fact daily before us is that pulverized earth retains the moisture and air as the handmaids of vegetation. Some experiments have lately been made the results of which favor these remarks, viz, "that soils afforded quantities of air by distillation somewhat correspond to the ratios of their values."

An article on the best method of reclaiming worn-out land was contributed by John Lang to the same society on December 12, 1810, and published in the second volume of the Memoirs, page 299, and following:

I conceive it a duty I owe the society to communicate through you the result of some experiments which I had set about for the purpose of ascertaining the best means of reclaiming old worn-out land. I had fondly listened to the method proposed by some, of improving with clover and plaster, without the use of lime, and determined to try it. The field which I pitched upon for my experiments contains about 14 acres; it had been cleared about fifty-three or fifty-four years ago and continued in constant cultivation for upward of thirty years without manure of any kind. Some old people now living say that they have seen as good crops of wheat cut from it as ever they saw; but it was kept in cultivation till the produce would no longer pay for the labor, and has been thrown out a common for more than twenty years, till I fenced it in. I had the whole of the field plowed early in the spring of 1808. In the month of May one part of it was plowed again, and sown with buckwheat; this buckwheat was plowed in when in blossom and the land sown with buckwheat a second time, which was likewise plowed in and sowed with rye.

The other part of the field was limed at the rate of 25 bushels to the acre and planted with corn. The lime which I used was of the hot kind, from a quarry which is generally approved of for land in those parts; makes very strong mortar for building, but is not used for plastering, being granulated and not very white. I suppose it to be similar to that described by Doctor Darwin, which he supposes to have been primitive lime, broken down by the action of water and petrified a second time, which he thinks is the strongest lime.

The following summer was very dry, which, together with the heat of the lime, I supposed to be the cause why the corn became stunted and produced almost nothing. In the spring of 1809 the land was plowed and sowed with oats and clover; the other part of the field which was now in rye was likewise sowed with clover at the same time, and as soon as the clover began to appear above ground the whole field was sowed with plaster.

At harvest the oats was a very good crop, the rye was tall and well eared, but rather thin; perhaps it was owing to this circumstance that the clover among the rye looked better and more plentiful than that among the oats. I had not seen it until Wednesday the 4th instant, when I found that part of the field which had been limed closely covered with fine clover, whereas on that part which was not limed almost the whole of it had perished last winter, and what plants remained were weak and sickly, and abundance of wood grass beginning to appear, with which the field used to be almost covered while it lay a common; whereas not one plant of it is to be seen on that part which was limed. From this I concluded that if the system of improving with clover and plaster without lime should succeed in the end, it must be by a number of repetitions of the same process, which would require time and labor equal to if not exceeding the expense of lime, and the result uncertain. I therefore ordered that the part of the field which had not been previously limed should be limed as soon as possible, twice plowed, and sown with rye and clover next spring.

It was the opinion of the man who farms for me, as well as of others who made observations, that I missed it by planting corn with the lime; that if I had sown oats and clover the first spring, I would have had a profitable crop, besides gaining a year by my improvement, which was lost by the failure of the corn crop and part of the strength of the lime exhausted to no purpose. I am fully aware of the objection which some have to oats as an exhausting crop, and therefore ill calculated for advancing the improvement of worn-out lands. At the same time that I disapprove of the absurd practice of some farmers of sowing oats and buckwheat, year after year, as the worst of all rotations, I am convinced from long experience that an occasional crop of oats is no more exhausting than wheat, rye, or corn; that it is an excellent nurse for clover, a profitable crop for the farmer, and the straw good fodder or litter, without which he can not get much dung, the value of which is not sufficiently appreciated by many of our farmers. Every kind of grain which ripens its seed is an exhauster; even clover, which is the most ameliorating crop which we know, if it is but a moderate crop and left standing until its seed is full ripe, instead of improving, will be found to exhaust the land.

Before I conclude I must take some notice of the mild lime which I mentioned in a note at the bottom of page 8. I then supposed the mild lime above mentioned to be the property of Mr. Barnitt, of Marlborough Township, but when I was with my friend, Mr. John Mills, on the 4th instant, he told me that Mr. Barnitt's lime is the hottest and strongest lime in that neighborhood, that the lime which I alluded to is the property of Mr. Baker, of Newlin Township. The two limes are not more than 2 or at most 3 miles apart; Mr. Mills's farm lays nearly in the center between the two, and he occasionally uses both. He says that it requires 130 bushels of the mild lime to go as far on land as 100 bushels of the hot lime, that the mild lime is in its effects on land somewhat similar to that of dung, as it gives out its strengh to the first crop, but in one or two crops more it is all gone; whereas, though the hot lime sometimes instead of helping rather injures the first crop, its good effects continue for many years. He showed me a clover field, one part of which had been manured with Mr. Barnitt's hot lime and the other with Mr. Baker's mild lime. I observed that wherever a heap of the hot lime had lain not a blade of vegetation of any kind had appeared, though Mr. Mills told me that every particle of it was shoveled off as clean as possible; but on that part of the field where the mild lime was put no such effects were produced. He told me further that the grain was best on that part where the mild lime was put, but the clover is greatly superior on the other part (it was all plastered alike), and I have no doubt that the succeeding crops will evince a decided preference in favor of the hot lime. I expect to procure specimens of both the above limes for the purpose of having them analyzed.

A very extensive examination of the use of gypsum as a fertilizer is also found in this volume. The article was prepared in 1797 and dedicated to George Washington, President of the United States, in the following language (page IX):

SIR: The following collection on the subject of the agricultural properties and uses of the gypsum, having been undertaken by me at your desire, I have thought there was a propriety in presenting it to you. However unimportant other parts may be, those which contain practical results I flatter myself will be useful.

I have had frequent occasions of knowing that the encouragement of agricultural improvement and information is among the favorite wishes of your heart. It is on this account and not with a design to give it an undue importance by placing it under your notice that I have been induced to inscribe to you this publication.

It is peculiarly consolatory when we can draw any portion of our comfort from our misfortunes. Your retirement from public life will afford you leisure and opportunities, by your patronage and example, to promote the interests of agriculture. Some compensation will thereby be afforded us for the loss we shall sustain by your resigning the helm at which you have so long, so wisely, and so safely steered our political barque.

Long may uninterrupted health, that first of blessings, enable you to enjoy the splendid evening of a life so much devoted to your country as to have been but little dedicated to yourself. And that you may be as happy as you have been eminently instrumental in making millions of your fellow-citizens is my sincere and ardent prayer.

I have the honor to be, with the most true and respectful esteem,
Your obedient servant,
RICHARD PETERS.

JANUARY 3, 1797.

In the preface to this article is a strong argument for the establishment of a department of agriculture, page IX:

And yet the greatest improvements in husbandry have been either suggested or made by those who were not professional farmers. If pecuniary assistance should be required out of the public funds it should be afforded. A cent expended, with propriety, to aid and reward genius and industry in pursuing agricultural experiments and researches will add an eagle to the public stock. This is applying nourishment to the root of the public prosperity.

Were it without example it would be surprising that legislatures, consisting for the most part of farmers, have done so little for the encouragement of a profession which is calculated, above all others, to produce additions to the common mass of property by creating countless supplies drawn from the earth.

In England the establishment of a board of agriculture under the patronage and pecuniary encouragement of the legislature is recent, but its advantages are incalculable.

In France agriculture is accounted, as it really is in all countries, the basis of public and private wealth and prosperity. Its patronage and encouragement are placed among the first objects of public attention, and radically interwoven with the principles and system of their national policy and government. Perhaps the period is not distant when the public mind here will be turned to this subject. Nothing will then be wanting toward the accomplishment of every-

> thing wished for by the friends to this important and invaluable art. They have received the highest gratification, and must conceive the strongest hopes by observing this subject recommended to the attention of Congress by the President, who has constantly mingled with his other patriotic solicitudes an unabating desire to forward agricultural inquiry and improvement.

On page XV he says further:

> I indulge a hope that men of chemical and philosophical knowledge will be induced further to examine and analyze this powerful substance, with a view more accurately to discover its agricultural properties and the causes of its operation on plants. The farmer, when taught by their discoveries and experiments, will be enabled to render this manure still more valuable by the most judicious modes of application. It will then be felt by the cultivators of our soil that science essentially promotes their interests and happiness. A practical conviction of the advantages derived from it will urge them to afford to literary establishments and men of useful learning the public and individual support they so justly merit.

The question of what is plant food was debated more than a hundred years ago, since it is said on page 93 of this article:

> Nothing has evidenced a greater diversity of opinion among the most eminent men than the question "What is the food of plants?" Nor do they agree about the nature of the air contained in vegetables. Some assert it is mere atmospheric air changed, or liable so to be, into fixed, by ebullition—phlogistic, by fermentation—or dephlogisticated by the sun, the light whereof operates a change in this air not produced in plants in the shade. Of what nature or species is the air contained in plaster; or whether this substance operates by its powers of attracting or retaining moisture, and decomposing, preparing, and communicating to plants the air the fittest for their nourishment, must be decided by others than practical farmers, to whom profitable effects are more important than the most learned and ingenious theories.

In an address by Doctor Mease before the Philadelphia Society for Promoting Agriculture, January 14, 1817, it is stated, on page XVI of volume 4 of the Memoirs of this Society:

> I state with pleasure that I have received information from a correspondent in Maryland of the discovery of large beds of alluvial deposits in Kent and Queen Anne counties similar to some of those found in various parts of west New Jersey, the utility of which as a manure in the sandy or light soils of that district you all know has been found, when cautiously used, to be very great; and I have no doubt that future researches in the peninsula, between the Delaware and Chesapeake, and indeed in every part of the tract constituting the ancient seacoast of our country, will discover similar deposits. The fertilizing properties of those substances can not fail of proving highly beneficial to the land in their vicinity; but I must caution those within whose reach they are not to depend entirely upon them for restoring the exhausted state of the soil; for, although independently of the good effects known to be derived from the mere circumstance of the stimulus given to plants by the new earth in which they grow, considerable advantage will follow the decomposition of seashells and other animal remains with which they are mixed; yet if successive and exhausting crops are taken from land dressed with the new substances; if part of the increased produce be not applied to the feeding of stock in the barnyard, and the manure thus obtained be not used to give body and life to the stimulated soil, their expectations of the treasure now dreamed of from the use of those substances will certainly not be realized. But the addition alone of manure will not answer all the desired end of the husbandman: the earth will sicken even of manure; rotations of green fertilizing or covering crops are indispensably necessary to recover the earth from the exhausting effects of an uninterrupted cultivation of tobacco and grain, or of any one crop. This is not mere theory; the experience of every judicious farmer or cultivator in Pennsylvania will support me in the propriety of this injunction.

A most interesting contribution to the subject of reclaiming the fertility of worn lands is in a paper by Mr. Richard Peters to the Philadelphia Society for Promoting Agriculture, on March 5, 1817.

Among the methods considered, Mr. Peters speaks of the farmyard so constructed as to save all the dung and urine; the value of fall plowing; the use of lime; the proper time of plowing in stable and yard manure; of deep plowing; of change of crops; the use of plaster; the value of orchard grass; explorations for refuse to be used as manures; the collection of summer dung; selection and change of seed on soil; the operation of fire on soils; ditching and draining; the utility of agricultural societies; habits of industry and sobriety, savings banks, and friendly and benefit societies are also discussed. In this paper, on page XXXIII, there is an interesting account of the effects of fire on soils. It reads as follows:

> The effects of fire on soils are well known in foreign countries to be salutary, and here proofs are not deficient. Various modes in which it has been applied are to be found in European books. When carried to excess it is, like all good things abused, no doubt injurious. Nor would anyone wish to destroy the inestimable vegetable matter of a sod capable of being completely decayed so as not to vegetate, for this would be unnecessarily wasting the means of restoring fertility by the cooperation (with this inert vegetable matter) of manures or materials for the food of plants in the earth or in the atmosphere. But where bulbs or other pests are otherwise indestructible, or the substratum be clay proper for burning into highly fertilized manure, there can be no reasonable objection to the application of fire. Denshiring or burnbaking is described in agricultural books, wherein its benefits are developed and the improper use of it pointed out. Burnt clay has been long known to be fertilizing, and so are the ashes of peat and turf. Even burning brush and straw on fields is proved to be almost incredibly fertilizing and productive. Burning the foul cover of wild grass and weeds before plowing for Indian corn, even in the spring, has, in frequent instances, destroyed the grub or the eggs of its parent. In what manner heat operates on soils is not essential, nor is the inquiry whether the effect be produced by the ashes or the mere application of fire. The facts are well ascertained, and that is enough for all practical purposes. Some soils may be less benefited than others, and with some burning may entirely disagree. Whatever may be the theory of or prejudices against this operation, it behooves us at least to try, if even on a small scale, a practice which has the approbation of eminent and successful practical and scientific agriculturists in Europe. And in this, as in every other operation, a farmer should know and calculate on the nature of his own soil, and thereby judge of the expediency and propriety of any practice.

As one means of improving the land the farmer is urged to read literature which will be useful in that direction. On page XLII Mr. Peters says:

> Read and do not slight either foreign or domestic books of reputation for principles and practice on agricultural subjects. Climates may and do differ, but principles are invariably the same. If you have, as you ought, a desire to be well acquainted with your art, gain some knowledge of subjects elucidating its principles, and particularly of chemistry, as connected with agriculture, although you need not aim at being a perfect chemist, nor qualify yourself as a disputant on theories and vain and unprofitable discussions which produce no beneficial results, but, on the contrary, bewilder those to whom information of plain principles and facts and practical lessons are the most necessary.
>
> Home's Principles of Vegetation, Darwin's Phytologia, Hunter's Georgical Essays, Anderson's Essays, Lord Dundonalds' Connexion of Agriculture with Chemistry, Davy's Agricultural Chemistry are among the books, giving a general view of principles, and books of practice you can obtain at pleasure. The former you can use as lawyers read Blackstone's Commentaries, and the latter as they apply to reports for detailed and practical information.

In regard to the prevailing habit of giving distilled spirits to laborers, it is stated on page 50:

> Associations should be formed to moderate, if it can not be totally abolished, the custom of dealing out to laborers ardent spirits—the most dangerous and

> destructive foes to the peace of a community and to the prosperity and happiness of individuals afflicted by a propensity to use them incontinently. Those who furnish the means of destruction are equally culpable with those who perish under their enticements.

An interesting book respecting the fertility of land is that written by Prof. Isaac Phillips Roberts, edited by L. H. Bailey, of Cornell University, entitled "The Fertility of the Land." In this work Professor Roberts takes up the problem of preserving and increasing the fertility of the soil. He defines the term "fertility" as commonly used in a special sense, meaning an abundance of nitrogen, phosphoric acid, and potash, but its true meaning is productive power. He states that land may contain any quantity of plant food in an inert state—that is, in a condition unsusceptible to plants, and yet, be sterile, whereas it may contain only a limited amount of plant food, and if that is available for the use of a plant it will be a fertile soil. He shows by analytical data that even poorer soils have an abundance of plant food, sufficient for several crops if it could all be utilized, while the richer soils in some cases have sufficient for two hundred or three hundred crops of wheat or maize. He says on page 19:

> This vast store of plant food is the farmer's stock in trade, the bank upon which he may draw. Its value can never be accurately determined, since a part of the plant food is not available, and since the power of the plant to secure that which is available depends upon many conditions, such as the correct preparation of the land, the kind of crops raised, the relative amounts of the various required constituents, and the amount of moisture present.

Again on page 32 he says:

> Since the soil and the subsoil contain such stores of potential fertility, and since tap-rooted leguminous plants bring to the surface abundant quantities of nitrogen with some mineral matter, and since many fields receive applications of farm manure from time to time, some far-reaching cause or causes must be present ever tending to seriously restrict production. It will be found that in this country the principal causes of low yields of farm crops are imperfect preparation of the land, poor tillage and hence a lack of available plant food, and insufficient moisture during some portion of the plant's life.

Professor Roberts in his book discusses the best method of tillage, the best means of preserving and applying manures, the best times of applying manures, the usefulness of nitrification, the home mixing of fertilizers, the value of lime, and many other problems connected with the conservation of soil fertility. I close this résumé of the history of soil fertility, its conservation and restoration by citing two classical works by American authors, well known and appreciated by all scientific agronomists, viz: Agriculture in Some of Its Relations to Chemistry, by F. H. Storer, and Soils, their Formation, Properties, Composition, and Relations to Climate and Plant Growth, by E. W. Hilgard.

A very remarkable document dealing with the fertility of the soil and its conservation is found in the annual oration delivered before the Chemical Society of Philadelphia on April 14, 1798. There are only a few copies of this document in existence. One of the most interesting of these is a copy given to Thomas Jefferson by the author himself, and now in the Library of Congress. On the title page is written in ink "To Thomas Jefferson, with the compliments of the author." The theme of the oration is a sketch of the revolutions in chemistry, by Thomas P. Smith, and it is dedicated to Robert Patterson, A. M., professor of mathematics in the University of Pennsylvania. At a meeting of the Chemical Society on April 14 the following resolution was adopted: "*Resolved*, That a copy of Mr. Smith's learned and ingenious oration be requested for publication. Extract from the minutes. George Lee, Jun. Sec'ry."

The concluding portion of this oration is as follows:

> The only true basis on which the independence of our country can rest are agriculture and manufactures. To the promotion of these nothing tends in a higher degree than chemistry. It is this science which teaches man how to correct the bad qualities of the land he cultivates by a proper application of the various species of manure, and it is by means of a knowledge of this science that he is enabled to pursue the metals through all the various forms they put on in the earth, separate them from substances which render them useless, and at length manufacture them into the various forms for use and ornament in which we see them. If such are the effects of chemistry, how much should the wish for its promotion be excited in the breast of every American! It is to a general diffusion of a knowledge of this science next to the virtue of our countrymen, that we are to look for the firm establishment of our independence. And may your endeavors, gentlemen, in this cause entitle you to the gratitude of your fellow-citizens.

DEFINITIONS OF SOIL FERTILITY.

The measure of the fertility of the soil is its ability under given seasonal conditions to produce a crop. The magnitude of the crop in those conditions affords a safe basis of judgment. It is true a crop does not get its whole nourishment from the soil. The carbohydrate matter, of which the largest part of every plant is composed, is taken from water and the carbon dioxid in the air or dissolved in the water. It is a self-evident axiom that the absence of any one essential element of plant food renders the production of a crop impossible. The absolutely essential substances necessary to plant growth are water, carbon dioxid, potash, and phosphoric and nitric acids. Essential elements are sulphur, lime and iron, magnesia and silica, and other mineral elements usually found in soils are also generally met with in plants, but are not deemed essential.

The soil plays a double rôle in plant growth—first it furnishes the physical support of the plant, and second it provides directly or intermediately the lime, potash, phosphorus, nitrogen, and sulphur, without which complete plant development is impossible.

The fertility of the soil is of two kinds, viz, temporary and continuing. Temporary fertility represents that excess of available plant food found in virgin soils and which rapidly disappears under continuous cultivation without fertilization. Temporary fertility also represents that increased power of production which a soil manifests under special tillage or by the application of manure and fertilizers. Continuing fertility is that which the soil maintains without the addition of fertilizing material and below which continual cropping can not reduce it. This properly represents the natural barrier interposed to prevent present agriculture from robbing future generations. It can not be doubted that if all the fertility of the soil could be put into enormous crops, say for a period of fifty years, the natural rapacity of man, from which even farmers are not free, would not be slow to utilize the gift. Future generations would be left to starve if nature permitted the enrichment of the present one. The phrase "continuing fertility" does not necessarily mean that there is no change in the degree of fertility or that there is any hard and fast line between it and temporary fertility. Experience has shown that in the great majority of cases a fertile virgin soil subjected to the usual practices in vogue in this country rapidly loses its fertility until a certain minimum production is reached. It then remains in this state with but little change for a long time. This fact has also been scientifically established by the celebrated experiments conducted at Rothamstead.

Now, if I understand the purpose of this discussion it is not how to preserve this minimum fertility but, on the other hand, how to preserve the higher fertility as shown in most virgin soils. On two previous occasions I have discussed this problem in detail, viz, in my address as chairman of Section C, of the American Association at the Buffalo meeting in 1886,[a] and the other in an address as retiring president of the American Chemical Society at Baltimore.[b]

In the address first mentioned I say: "The exportation of agricultural products becomes, therefore, a slow but certain method of securing soil exhaustion, and this accounts for the fact that countries, or those portions of countries which are devoted to almost exclusive agricultural pursuits, thus causing a continuous exportation of agricultural products, become the homes not of the richest but of the poorest communities."

It would be useless to deny in this connection that our own country, with a soil enriched by centuries of accumulating nitrogen, has grown rich from its agricultural exports. But when the last of our virgin soil shall have been placed under cultivation a continuous stream of such exports will certainly impoverish the nation and reduce all who practice such agriculture to the condition which has already been reached by those who have for years grown tobacco, corn, cotton, and wheat on the same soil and sold the products without paying back to the field the percentage of profits which was its due.

On the other hand, the farmer who is fortunate enough to be permitted to patronize the home market, who sells his maize and takes home a load of manure, adds not only to the plethora of his purse but also to the fertility of his soil.

Thus in the light of agricultural chemistry we see clearly the deep scientific basis of the teachings of political economy which show the value of the home market. While, therefore, the statement made at the commencement of this address, that the chief factor in the prosperity of a country is its agriculture, remains in every sense true, yet from the data discussed it as readily appears that agricultural prosperity is most intimately connected with the advancement of every other industry. Agricultural chemistry teaches the farmer to welcome the furnace and the mill, for in their proximity he secures a sure return to his fields of the plant foods removed in his crops.

We have seen by the foregoing discussion that, without any artificial additions, the soil, excluding the subsoil, contains enough of the two most important and valuable mineral constituents of plants to produce an average crop annually for 250 years. In point of fact, however, the impoverishment of the soil takes place at a much slower rate than this theory would indicate. It would, indeed, be a sorry thought to consider that in a quarter of a millennium the agricultural area of the earth would be incapable of producing further yields. Doubtless much of this reserve food is brought from the subsoil, and if it be possible for the subterraneous stores of these materials gradually to work their way surfacewards, even the remote future need not fear a dearth of them.

---

[a] Proceedings of the Am. Assn. Adv. Sci., vol. 35.

[b] Journ. Am. Chem. Soc., Jan., 1894.

There is also a certain conservatism in crops, a vegetable "good breeding," which prevents the growing plant from taking all the food in sight. As long as there is abundance the plant is a hearty eater, but when the visible quantity of food falls to a certain minimum it remains for a long time without any rapid diminution. This fact is well illustrated in the experiments of Lawes and Gilbert at Rothamstead, where wheat was grown on the same unmanured field for forty years in succession.

In the "Summary and general conclusions" derived from these experiments, these celebrated agronomists say: "A soil which in the ordinary course of agriculture would have received an application of manure before another crop was sown, has produced crops of wheat in succession, averaging 14 bushels per acre, solely by means of its existing fertility. * * * The stock of potash and phosphoric acid has been largely reduced. Although so much soil fertility has been removed, the stock that remains would appear to be sufficient to grow crops of wheat for a very long period; the produce, however, must, in process of time, necessarily be lower than it has hitherto been."

THE ROTATION OF CROPS.

The great utility of a proper rotation of crops in conserving the magnitude of the yield is one of the best known principles in scientific agriculture. Various and ingenious theories have been presented to account for this benefit. In this connection it seems to me desirable to point out the true cause of the benefit derived from the rotation of crops. There is nothing mysterious or occult in plant growth. As in the case of animals, plant growth consists in pure chemical transformations. There is no such thing as "vital principle" or "mysterious force," or "supernatural influence." Every operation is based upon the principles of chemistry. The course of the sap in the plant, the nourishment of the germ, the transformation of the carbon dioxid of the air, the building of inorganic into organic products, the building up and decomposition of plant materials are all governed by the laws of chemical science.

Attention has already been called to the fact that the sources of plant food are so distributed in nature that they become available little by little, thus securing for future generations the possibility of life which would be speedily denied them if soil fertility could be utilized within a few years. The well-known principle of the law of the minimum, it seems to me, is the true explanation of the benefit of crop rotation. If all crops used their foods in the same proportion, there could be little benefit derived from crop rotation, but as in the case of animals so it is with plants. Some animals live exclusively on flesh foods; others live exclusively on vegetable foods; others on mixtures of these foods in varying proportions. It is evident that if all animals lived on flesh foods starvation would soon take place. It is evident, further, that if all animals lived on vegetable foods the food problem would be immensely increased in difficulty, and if all animals lived on the same proportions of vegetable and animal foods there would be a stringency in some quarters due to the exhaustion of one or another of the principles of the foods. The same law holds good with the plant. While all plants live on essentially the same kinds of food, the quantities of any particular kind required vary in every plant. It is only necessary to study the life history of any one plant and compare it with the life history of another to show this fact. For instance, a study of the nutrition of wheat as compared with the nutrition of the sugar beet will indicate in probably an extreme manner the variations of the proportions of the various plant foods required. Hence if a crop, such as the sugar beet, is grown continuously on a field without the administration of any artificial food, the particular character of the plant food furnished by the soil which is most required is soon reduced to a minimum of production, while at the same time other varieties of plant food may still exist in abundant proportions. In this condition the sugar beet grows only with its minimum crop. If any cereal, such as wheat, be planted in the same field, all the elements necessary to the production of wheat may still be present in abundance and the maximum crop of wheat will be produced. Since plant foods are furnished constantly in soils chiefly by progressive decomposition and by capillary translation, the best results are necessarily secured by changing crops. This principle will account for the principal benefit secured by crop rotation. There are of course other factors, such as character of the cultivation, the variations of the bacterial flora, the increasing or decreasing acidity, which play a prominent but not a dominant rôle. But in each of these cases the general law of supply and the general law of the minimum hold good.

LOSSES DUE TO INSECTS.

PART I. INSECTS AS A CHECK ON AGRICULTURAL PRODUCTION AND AS A SOURCE OF WASTE TO ACCUMULATED SUPPLIES.

By C. L. Marlatt,
Bureau of Entomology, U. S. Department of Agriculture.

INTRODUCTION.

The value of the farm products of the United States for the year 1907 is estimated by the Secretary of the United States Department of Agriculture at $7,412,000,000 at the point of production. Of this total $4,742,000,000 are plant products. The accumulated stores of previous years of such staples as the grains, tobacco, etc., will easily bring the value of plant products of this year, subject to loss from insects, to upward of $6,000,000,000. To one familiar with the work of important insect pests on farm crops, stored grains, and other stored products entering into this total, it is not difficult to approximate the probable shrinkage due to insects. The detailed description of such shrinkage which follows indicates that it will rarely fall below 10 per cent of the total value, and in the case of certain important farm staples may, in years of excessive damage, amount to 50 per cent. For the cereal grains and other important field crops a minimum 10 per cent rate of loss from insects has been adhered to. The rate of loss, however, is much heavier with certain other classes of farm products, such as truck crops and fruits, being certainly not less than 20 per cent for the former and 30 per cent for the latter. As will be indicated more exactly farther on, this resulted for the year 1907 in a shrinkage in value of all plant products of the farm of $552,500,000. To this must be added the injury occasioned by insect pests to farm products in storage, amounting to at least $100,000,000, making a total tax in 1907 of $652,500,000 on the plant products of the farm chargeable to insects, and this is approximately the annual tax which insects impose on such products in the United States. That this estimate, which at first may seem absolutely preposterous, has really a reasonable basis will be indicated, it is believed, by the more detailed consideration of the nature of the losses which follows.

BASIS OF ESTIMATES.

The estimate of losses is based on the farm price of the crop actually harvested, and does not, therefore, take into account the possible reduction in value which would follow the marketing of the larger crop. While it is true that prices are regulated by production, the factor of distribution, especially in the case of cereals, often predominates, so that large crops may bring good prices and small crops low prices. During the last fifteen years, for example, the price of wheat in this country has exhibited little if any relation to our own production. The bumper wheat crop of 1901 of nearly 750,000,000 bushels brought to the farmer 23 cents a bushel more than the crop of 1894, which was 300,000,000 bushels less, or but little more than half the production of 1901; and for several years the farmer has been getting higher prices for wheat on crops larger than the average.

Some definite means of estimating losses must be assumed, and any effort to scale down these losses by reckoning possible enhancement of the market price, in view of the conditions just cited, would come more in the category of pure guesswork and be open to quite as great objection as the plan adopted. As an offset to possibly enhanced values due to shrinkages occasioned by insects, moreover, are certain very legitimate items of cost. A very considerable item of loss properly chargeable to insects is the annual expenditure devoted to their control, which, except in the case of certain fruit and truck crops, has not been considered in the estimates. This amounts to a large percentage of the value of the crop in the case of orchard fruits, truck crops, and of such field crops as cotton and tobacco. In the case of the cereals, protection is chiefly secured by farm practices, such as rotation of crops, variations in the time of planting, etc., and this also applies, to some extent, to cotton, tobacco, and truck crops. In estimating the losses due to the codling moth, for illustration, it is shown that a sum of $5,000,000 a year is expended in spraying apple trees, allowing a cost of only 10 cents per tree for one-fourth of the bearing trees. In the case of citrus fruits the cost of gassing and spraying ranges from 10 cents to $1.50 per tree.

Another legitimate class of losses not included in the estimate is the secondary losses which necessarily result from diminished products. For example, the excessive reduction in winter wheat through the Hessian fly ravages in 1900 put a serious check upon milling operations throughout the region worst affected and caused very heavy loss in this field of industry. Similarly a shortage of cotton may so increase the values as to lead to the shutting down of cotton mills, as has been illustrated recently. A shortage of grains means a corresponding loss to railroads and other transportation companies and to shippers. In other words, any material shrinkage in an important product starts a train of losses to the end of the chapter, the total amount of which is quite beyond calculation or estimate.

The writer believes that these omitted items of loss will make good any difference of price which might result from the larger crops if insect damage were entirely eliminated.

Irrespective of the monetary consideration is the actual material loss in products, which is absolute so far as the consumer is concerned. From the standpoint of the producer, also, the action of injurious insects is to put a check on production, and the shrinkage of crops represents wasted effort. In other words, were it not for these pests, a lessened acreage and a saving in labor would produce an equivalent crop.

A general view of the relation of insect losses to the important staples is given in the table below. The value of plant products is based on the report of the Secretary of the United States Department of Agriculture for 1907. The last two columns, indicating the shrinkage due to insect work, are based on the crop actually harvested; that is to say, except for such damage the crop would have been 10 or 20 per cent greater.

Values of plant products for 1907 and losses chargeable to insect pests.

Product.	Value.	Percentage of loss.	Amount of loss.
Cereals	$2,378,000,000	10	$237,800,000
Hay	660,000,000	10	66,000,000
Cotton	675,000,000	10	67,500,000
Tobacco	69,000,000	10	6,900,000
Truck crops	[a] 340,000,000	20	68,000,000
Sugars	64,000,000	10	6,400,000
Fruits	[a] 220,000,000	30	66,000,000
Farm forests	[a] 150,000,000	10	15,000,000
Miscellaneous crops	[a] 189,000,000	10	18,900,000
Products in storage	....	....	100,000,000
Total	4,745,000,000	....	652,500,000

[a] Estimate only.

An explanation of the nature of the loss and method of computation for the different products as above classified follows:

INSECT DAMAGE TO CEREAL CROPS.

Only the losses to the two most important cereals, corn and wheat, will be discussed in this paper, as the injury to oats, barley, rye, etc., will average about the same percentage and need not be specifically analyzed.

INSECT DAMAGE TO CORN.

In point of quantity and value, corn is the leading cereal crop of the United States. Its annual farm value in later years has been upward of $1,000,000,000. While less subject to insect damage than wheat, the next most important cereal, the corn product would be considerably greater were it not for important insect pests. The work of several of these is obscure, and many farmers are entirely ignorant even of the existence of some of the worst enemies of this crop. In this last category falls the work of the corn root worm (*Diabrotica longicornis*), which ordinarily passes unnoticed, or at least is often misunderstood. The larva of this insect feeds on the roots of young corn, and in regions of bad attack may cause almost an entire loss of the stand. The corn root worm, together with one or two allied species working in substantially the same way, causes an annual loss of at least 2 per cent of the crop, or some $20,000,000.

Perhaps the next most important insect pest of this cereal is the bollworm or earworm. This insect, as shown by Mr. A. L. Quaintance, of this bureau, probably attacks from 90 to 100 per cent of the ears of sweet corn throughout the country, and in the South practically an equal percentage of the ears of field corn, as shown by actual counts in the field made during the years 1902 and 1903. The average loss in the number of kernels to an attacked ear is 15 per cent, or, if allowance be made for the smaller size of the terminal kernels, at least a loss of 7½ per cent. The percentage of loss is less in the great corn areas of the Northern and Middle States, but a 2 per cent loss for the United States chargeable to this insect is certainly well within the limits of actual damage, and would, for the corn crop of 1904, indicate a loss of over $20,000,000.

Of perhaps equal importance to this crop are the depredations of the chinch bug. Chinch-bug injury is, as a rule, more marked where corn is grown in the neighborhood of wheat or small grains, and in such cases the migration of the chinch bug from wheat to corn may often result in the total destruction of considerable areas of corn. The chinch bug is a strong flier also, and at the period of migration in midsummer corn is often attacked, the loss in the case of this cereal being, however, very much less than in the case of wheat. For the country as a whole, however, the loss from the chinch bug, taking one year with another, will probably be 2 per cent of the crop, or, estimating from the crop of 1904, $20,000,000.

Every year in different sections of the country there is notable injury to corn by such insects as billbugs, the various wireworms, cutworms, army worms, stalk borers, various species of locusts or grasshoppers, corn plant lice, and others, to a total of fifty fairly important species. These minor pests undoubtedly cause a loss of an additional 2 per cent, making a total annual injury of 8 per cent and indicating a loss of $80,000,000.

INSECT DAMAGE TO WHEAT.

Of the cereal crops of this country wheat suffers most from insect depredations. Of the large number of insects which depredate on this cereal, the three important species are the Hessian fly, the chinch bug, and the grain plant louse, using the latter term to include several allied species which work in much the same manner.

The chinch bug is notably a wheat pest, although its damage to other cereals and forage crops is very considerable. The losses from the depredations of this insect on wheat in single States have ranged between $10,000,000 and $20,000,000 in one year. A very reasonable average annual estimate of loss, taking the country as a whole, would be 5 per cent of the value of the wheat crop, which would indicate about $20,000,000 a year chargeable to this insect.

The Hessian fly is distinctly a wheat pest, although doing some damage also to rye and barley. The losses due to it will be considered in detail to indicate their nature specifically and to illustrate the exactness and reliability which may sometimes characterize records of this kind relating to particular pests of a single crop.

The season of 1900 is notable in Hessian-fly annals as exhibiting the most destructive work of this pest in recent years. The fly was very generally present throughout the main wheat-growing districts of the Ohio and Mississippi valleys, but its ravages were that year concentrated particularly in Ohio and Indiana. The statistics of the acreage and yield of wheat and the value of the crop for that year for the States mentioned reflect very plainly the loss occasioned by this pest. The wheat area in these two States in 1900 and the years immediately preceding was about 5,000,000 acres. Chiefly on account of the ravages of the Hessian fly more than half of this acreage (2,577,000 acres) had been abandoned and planted in other crops prior to May 1, 1900, as shown by the records collected by the Bureau of Statistics of this department. The abandonment was about 40 per cent for Ohio and 60 per cent for Indiana. The cost of the preparation of soil, planting, and seed wheat for this abandoned acreage is all that need be reckoned, inasmuch as it was possible to use the land for other crops, such as corn or oats. The loss in labor and material indicated will approximate $3.50 per acre, giving a total of over $9,000,000. Of the remaining wheat acreage, the average yield per acre for this year in Ohio was 6 bushels, as against 15.3 bushels for the year following, 14.2 bushels for the year previous, and nearly 17 bushels for the years 1897 and 1898. For Indiana, the yield per acre in 1900 was only 5.3 bushels, as contrasted with 15.8 bushels for 1901, and 15.6 and 9.8 bushels, respectively, for 1898 and 1899. In other words, a decrease of nearly two-thirds in the yield per acre is shown for these two States for the area in wheat which was left for harvesting. The Hessian fly does more or less damage every year, which reduces the average yield per acre, and, therefore, if such damage be eliminated the average yield per acre should be in the neighborhood of 15 bushels, indicating a loss for that year of nearly 10 bushels per acre for the area harvested, or, for the two States, of 24,230,000 bushels of wheat, of approximately a farm value (at the low price for that year) of $15,000,000. This loss, combined with the $9,000,000 indicated for abandoned acreage, gives a total direct loss for Ohio and Indiana of over $24,000,000. These figures, enormous as they are, are based on the careful statistical records of the acreage, yield, and prices of 1900 collected by the statistician of the department, working entirely independently of the Bureau of Entomology.

During this year the damage in other wheat-producing States was notable. For example, more than 20 per cent of the planted area of Michigan was abandoned, and lesser amounts in other States, with great shrinkage in the yield which was actually harvested. The loss, therefore, for this single season due to the Hessian fly undoubtedly approached $100,000,000.

The losses occasioned by this insect, while showing great fluctuation, as indicated, are an annual tax on the wheat crop. Except in cases of exceptional severity they pass, however, comparatively unnoticed. For example, the Hessian fly was not especially complained of in 1904, yet the agent investigating the insect enemies of cereal crops in the Ohio Valley reported that many fields showed injury to the extent of from 50 to 75 per cent. In comparatively few years this insect causes a loss less than 10 per cent of the crop, or the equivalent of a shrinkage of over 50,000,000 bushels in the yield, or, on the valuation of the crop for 1904, of over $40,000,000.

The losses due to grain plant lice are often very heavy, as may be illustrated by the extraordinary invasion of the so-called green bug in Texas and Oklahoma in the season of 1907. Statistics of these two States only are given, but the green bug spread its damage extensively into Kansas and was the occasion of more or less loss to small grains throughout the United States east of the Rocky Mountains. In Texas and Oklahoma, however, the damage was excessive, and over vast areas the wheat and oat crop was totally destroyed. The shortage of these crops in these States is to be attributed practically to this one source, as the conditions were otherwise favorable for an average yield. As shown by the records of the Bureau of Statistics of this Department, there was a reduction of over 24,000,000 bushels in yield of wheat over the preceding year (1906) from a similar acreage planted for Texas and Oklahoma, and a shrinkage of more than 35,000,000 bushels of oats. The grain thus lost represents an approximate farm value of $32,000,000. Some of this loss was made good by the replanting of the ravaged fields in other crops, but the cost of the preparation of the soil for planting and the seed grain for the abandoned acreage (nearly three-fourths of the area planted), and the very much lessened yield of the acreage actually harvested, makes a large percentage of this amount an actual loss. The plant louse occurs every year throughout the Mississippi Valley and eastward, always inflicting more or less damage, and with a favorable season may any year cause a loss similar to that witnessed in Texas and Oklahoma in 1907. The average annual loss from this and other plant lice certainly amounts to 2 or 3 per cent of the wheat crop.

The many other insects depredating on wheat, including grasshoppers, the wheat midge, several species of sawflies, and the cutworms and army worms, will swell the total of loss to at least 20 per cent of the crop. In other words, were it not for the attack of these pests the wheat crop would be one-fifth greater than it now is, or would have an additional value of approximately $100,000,000.

The insect damage to other cereal crops probably falls short of 10 per cent. A 10 per cent average, however, for all the cereals is certainly a reasonable one and is the basis of the loss indicated in the general table.

INSECT DAMAGE TO HAY AND FORAGE CROPS.

The damage by destructive insects to hay and forage crops is more obscure and less generally understood than in the case of any other farm products. Certain of the larger insects depredating on hay and forage crops are commonly known. These include the various species of locusts or grasshoppers, army worms, and cutworms. Very little understood and generally overlooked, however, are the webworms and small grass worms (*Crambus* spp.) which work about the base or roots of the plants, and which are so abundant that at certain seasons the moths flit up in front of one at every step. Swarming also in grass lands are many species of minute leaf hoppers which reduce the yield enormously, their small size being more than offset by their prevalence and numbers. Obscure, but very important also, are the white grubs which work on the roots and often kill the grass outright over large areas, and everywhere tax production heavily. In the same class in habit are the meadow worms or leather jackets, the grass-root feeding larvæ of the crane flies. A 10 per cent shrinkage from these and other pests in grasses and forage plants is a minimum estimate.

INSECT DAMAGE TO COTTON.

The principal insect depredators on cotton are the cotton-boll weevil, the bollworm, and the leaf worm. Many other insects, however, inflict minor damage. The loss chargeable to the boll weevil, from the very conservative estimate of Mr. W. D. Hunter, the agent charged with the study of this insect in Texas, represents, for the year 1907, some $25,000,000.

The bollworm is chiefly destructive in the southwestern cotton-producing States of Mississippi, Oklahoma, Arkansas, Louisiana, and Texas, causing a damage of from 2 to 60 per cent of the crop; it has been very conservatively estimated by Mr. A. L. Quaintance at 4 per cent of the crop and indicates an annual loss of some $12,000,000. East of these States comparatively little damage is done by the bollworm.

The cotton-leaf worm in years of excessive damage, before arsenical poisoning was a common practice, caused a loss of $20,000,000 to $30,000,000. The present damage is very much reduced, but with the increased acreage of cotton an annual loss of from $5,000,000 to $10,000,000 may be conservatively estimated.

Without counting the losses due to a host of minor insect depredators, we have already a total annual loss of more than $40,000,000 chargeable to three important insect pests of this staple.

INSECT DAMAGE TO TOBACCO, TRUCK CROPS, SUGAR CANE, ETC.

Detailed statements relative to insect losses to the crops enumerated above will not be attempted in the space at command. All are subject to attacks of important insect pests, and a reasonable estimate of the annual damage is 10 per cent of the value of the first and last named crops, and fully 20 per cent in the case of truck crops. Vegetables and other truck crops are especially subject to insect injury; furthermore, there is always a large expenditure in the control of insects, the items of which and of actual damage together probably making the tax due to insects double the normal 10 per cent rate.

INSECT DAMAGE TO MISCELLANEOUS CROPS.

A great many minor crops enumerated in the census of 1900 can not be discussed separately; consequently, the valuation of the crops is lumped together and a 10 per cent loss chargeable to insects estimated on the whole, which seems reasonable in view of the examinations already made of the more important farm products.

INSECT DAMAGE TO STORED PRODUCTS.

The estimates given in the foregoing discussions relating to vegetable products give the shrinkage due to attacks of insects to growing and maturing crops. After these crops have run the gauntlet of insect enemies during their entire period of growth, notably the cereal and forage crops, tobacco, and certain truck crops, they are still subject to the inroads of another class of insect depredators while in storage on the farm, or, in greater accumulations, in elevators and mills, or, again, while in transit, especially in the case of long shipments by sea. The cereals are kept in storage until consumed, which means a considerable period for the bulk of the crop. The various grain weevils and beetles, flour moths, and other insect pests which depredate on stored grains frequently cause great losses, and an estimated injury of 5 per cent is a reasonable and probably minimum figure. Computing this percentage, therefore, on the valuatio of the cereal products for 1907 we have an annual loss of more tha $100,000,000.

The location of food products for human consumption is in th house storeroom and kitchen, and often this last opportunity fo insect damage is improved by various species of the stored-grai pests already referred to. Animal products are attacked by larde beetles, ham beetles, etc.; fruits by various fruit and vinegar flies; an woolens or household furnishings by carpet beetles, clothes moths silver fish, etc.

Cured tobacco is especially subject to insect attack and damage, th most important source of injury being a minute insect known as th cigarette beetle, which not only eats into cigarettes but into all othe forms of cured tobacco. It is now widespread in America, occurin in practically all factories, warehouses, and retail establishments, an is frequently the cause of very heavy losses.

In the general table a total loss of $100,000,000 is indicated fo insects attacking stored products. This is covered by the loss fo cereal products alone, and if the other items of loss just enumerate were included a considerable increase in the estimate could legitimately be made.

CONTROL OF INJURIOUS INSECTS.

The enormous annual loss which may now be fairly charged t insect pests can be very much limited by the more general adoptio of known methods of control and by thoroughgoing investigation to discover other practicable means of prevention. In no country i the world has the problem of insect control been more energeticall taken up than in the United States, both in the work of the Burea of Entomology of the United States Department of Agriculture an of the state and experiment station entomologists of the variou States. The methods of controlling important insect pests whic have resulted from the studies of the last twenty-five years, and whic have been adopted by the more progressive farmers and fruit growers have already put a large limitation on insect losses. As a genera proposition, fruit growing in this country would practically come t an end if sprays and other means of control, which have resulte from the studies of the problem by experts, were discontinued, and vast increase in the losses to cereals and other crops and to anima products would result from neglect of known measures applying i these fields.

As illustrating the saving from insect losses now effected and pointing to still greater ones, which will come as a result of future wor and the more general adoption of known methods, a few commo examples may be given. The cotton worm, before it was studied an the method of controlling it by the use of arsenicals was made common knowledge, levied in bad years a tax of $30,000,000 on the cotto crop. The prevention of loss from the Hessian fly, due to the knowledge of proper seasons for planting wheat, and other direct an cultural methods, results in the saving of from $100,000,000 to $200,000,000 annually. Careful statistics show that the damage from th codling moth to the apple is limited two-thirds by the adoption o arsenical sprays, banding, and other methods of control, representing a saving of from $15,000,000 to $20,000,000.

The existence and progress of the citrus industry of California were made possible by the introduction from Australia of a natural enemy of the white scale, an insect pest which was rapidly destroying the orange and lemon orchards, this introduction representing a saving to the people of that State of many million dollars every year. The rotation of corn with oats or other crops saves the corn crop from the attacks of the root worm to the extent of perhaps $100,000,000 annually in the chief corn-producing regions of the Mississippi Valley. The cultural system of controlling the boll weevil is already saving the farmers of Texas many millions of dollars, and, in fact, making the continuance of cotton growing possible, and scores of similar illustrations could be cited.

PART II. INSECT DAMAGE TO FRUITS.

By A. L. Quaintance,
Bureau of Entomology, U. S. Department of Agriculture.

INTRODUCTION.

As indicated in an introductory paragraph in Part I, the insect injury to orchard and small fruit is exceptionally heavy, and in spite of the corrective measures there is a tax of at least 30 per cent on production. Remedial measures are of the greatest importance in this field, and were it not for the insecticide and other treatment now practiced the commercial fruit interests of this country would be practically annihilated. In addition to the horde of native species which have in great measure left their native wild food plants and attack orchard products, many of the most serious fruit insect enemies of the Old World have been introduced into this country, often without their natural checks, for which and other reasons they have here become excessively injurious. The control of most orchard insects takes the form of spraying, and while this is relatively very expensive, fruit spraying yields a larger percentage of benefit than is the case with many other crops.

The detailed examination of the subject which follows covers the leading insect enemies of the principal deciduous fruits, such as the codling moth, San Jose scale, peach-tree borers, grape phylloxera, etc. The citrus and subtropical fruits have not been specifically considered, but with these the rate of loss, together with the cost of protective treatment, is fully as heavy as with the deciduous fruits. A total insect tax on deciduous fruits of more than $66,000,000 is indicated, and this is really a moderate estimate, as will be seen from the discussion of the several items entering into this total. The cost put down for spraying trees and the losses to fruit are minimum charges, and are very generally exceeded in actual orchard practice and experience.

THE CODLING MOTH.

The codling moth has been depredating on the American apple crop for upward of one hundred years, and during this period has destroyed fruits to the value of several hundred millions of dollars. Within the past twenty years a very large sum has been expended in its control.

The average annual apple crop from 1897 to 1907, as shown by statistics obtained by the American Agriculturist, is approximately 37,000,000 barrels. Assuming that there is a 25 per cent loss of fruit from this species, the figures of yield given represent three-fourths of the total crop—that is, the shrinkage in yield is about 12,330,000 barrels, which, with a valuation of $1.25 per barrel, represents about $15,500,000. Deducting from this amount the possible value of the fruit for cider, vinegar, etc., at 30 cents per barrel, there is a net loss of $11,750,000.

Assuming that but one-fourth of the total number of apple trees are sprayed each year, and at a cost of 10 cents per tree, the cost of treatment is about $5,000,000.

The total annual tax of this species to the apple growers of the United States thus amounts to about $16,750,000, as explained more in detail below:

DAMAGES BY THE CODLING MOTH.

(*Carpocapsa pomonella.*)

In estimating the annual loss from this insect to apple crop, the American Agriculturist figures of crop were used, and the average crop of the past ten years was taken as a basis:

Average crop, 1897 to 1907, inclusive (barrels)	37,000,000
Estimated that only one-half of total number of trees are in bearing any one year (off year, cold, etc.), crop from, approximately (trees)	100,000,000
Estimated that only one-half of this number of trees are sprayed	50,000,000
Estimated that in unsprayed orchards there is a loss each year of 50 per cent of crop.	
Shrinkage in yield, 25 per cent of whole crop, or 50 per cent of crop on the 50,000,000 unsprayed trees (one-third of 37,000,000 barrels)	12,333,333
Value of shrinkage, at $1.25 per barrel	$15,416,666
(Average price per barrel for past ten years at principal eastern markets was $2.65.)	
Less value of culls, at 30 cents per barrel	3,699,999
Net loss on crop	11,716,667
At 10 cents per tree, cost of spraying 50,000,000 trees	5,000,000
Present loss and cost of treatment	16,716,667

THE SAN JOSE SCALE.

The outlay necessary to bring an orchard to bearing age is considerable, amounting under favorable conditions of management to from 50 cents to $1 per tree. The destruction of trees by scale or other causes before fruiting begins, or later, represents therefore a loss of invested capital aside from the loss of possible dividends from the fruit produced. Losses from the San Jose scale have been occasioned largely by the wiping out of capital invested in orchards by the destruction of the trees. Since its introduction into California in the early seventies, and its appearance in the East some fifteen years later, losses of this character to orchards and other plants have been perhaps not less than fifty or sixty million dollars.

A conservative estimate of its injuries at the present time indicates that of the 350,000,000 trees of the more important deciduous fruits, as given in the 1900 census, about 80,500,000 are infested. It is believed that three-fourths of this number, or 60,000,000, are now being treated, resulting in the preservation of trees worth at least $46,000,000.

The annual loss resulting from failure to spray amounts on the same basis to about $5,000,000. The cost of treating the 60,000,000 trees, at 9 cents each, is about $5,500,000, aggregating a total annual charge against this species of $10,500,000, as detailed below.

DAMAGES BY THE SAN JOSE SCALE.

(Aspidiotus perniciosus.)

The number of trees subject to infestation as given by the 1900 census was taken as a basis. The number of trees infested was determined by estimating the percentage of infestation in the various States where the scale is known to occur.

Apple trees infested	40, 383, 339	Now sprayed	30, 287, 505
Peach and nectarine	27, 911, 032	Do	20, 933, 274
Pear trees infested	3, 116, 884	Do	2, 337, 663
Plum and prune infested	9, 014, 316	Do	6, 760, 737
Total	80, 425, 571	Total	60, 319, 179

Value of orchard interest now saved by spraying:	
30,297,505 apple, at $1 per tree	$30, 279, 505
20,933,274 peach and nectarine, at 50 cents	10, 466, 637
2,337,633 pear, at 75 cents	1, 753, 224
6,760,737 plum and prune, at 50 cents	3, 380, 368
	45, 879, 734
Loss from San Jose scale:	
One-fourth of infested apple trees, not sprayed, 10,095,834, at $1 each	10, 095, 834
One-fourth of infested peach and nectarine trees, not sprayed, 6,997,758, at 50 cents	3, 488, 879
One-fourth of infested pear trees, not sprayed, 779,221, at 75 cents each	584, 415
One-fourth of infested plum and prune trees, not sprayed, 2,253,579, at 50 cents each	1, 126, 798
	15, 295, 917
Assuming that only one-third of these trees die each year, annual loss becomes	5, 098, 639
Cost of treatment, 60,319,179 trees, at 9 cents each	5, 429, 626
Total annual loss of trees and cost of treatment	10, 528, 265

PEACH TREE BORERS.

Throughout its area of culture the peach is subject to attack from *Lepidopterous larvæ*, which feed on the inner bark, at the base of the tree, on the roots, or along the trunk. Young trees are especially injured and often killed, and older trees are often so weakened that normal crops are not produced. Using the 1900 census figures as a basis, at a valuation of 50 cents per tree and an estimated injury of 10 per cent, the losses from this species become $5,000,000.

There is also a large expenditure in labor in worming trees (the method principally relied upon to control the species), amounting perhaps to at least $1,000,000, making a total charge against this species of $6,000,000.

DAMAGES BY PEACH TREE BORERS.

(*Sanninoidea exitiosa; S. opalescens; Synanthedon pictipes.*)

The number of trees as given by the 1900 census was taken as a basis.

Number of peach and nectarine trees approximately	100,000,000
Value, at 50 cents per tree	$50,000,000
Estimated an annual shrinkage in value of 10 per cent	$5,000,000
Estimated cost of treatment, mostly digging out	1,000,000
Total	$6,000,000

GRAPE INSECTS.

The grape suffers severely from insect attack. The *Phylloxera* in California, to which State its injuries are principally confined, causes an estimated annual deterioration in condition of vineyards of not less than 5 per cent. On this basis its injuries represent a loss of about $3,500,000.

The grape root worm for some years has threatened the grape industry in the Erie and Chautauqua grape belts in New York and Pennsylvania, and has done a large amount of damage in Ohio. Considering its injuries in this territory only, an estimated annual deterioration in the condition of vineyards of 10 per cent results in the loss of something more than $1,750,000. If to this be added all expenditures for treatment, there is a total of over $2,000,000 which this species taxes the grape growers of this limited territory.

The grape leaf hopper, another important enemy of the vine, occurs all over the United States, and is present in vineyards every year, in many instances being excessively destructive. At the low estimate of injury of 2.5 per cent for the United States as a whole, the deterioration in condition of vines resulting from the attack of this species is about $2,250,000. There are numerous other grape pests that locally often become seriously destructive, as the rose bug, grape berry moth, flea beetle, leaf caterpillars, etc. The total loss from these several pests of $1,000,000 each year, including money spent in their control, will be quite conservative. The annual loss throughout the country to vineyards therefore is about $8,750,000.

DAMAGES BY GRAPE INSECTS.

[Figures of 1900 census were taken as a basis.]

Phylloxera.

Number of vines in California	90,686,458	
Value, at 75 cents per vine	$68,014,843	
Estimated 5 per cent annual shrinkage in value of vineyards from *phylloxera* attack		$3,400,742

GRAPE ROOT WORM (*Fidia viticida*).

Number of vines in Pennsylvania, Ohio, and New York (principal area now seriously injured)	37,801,289	
Value, at 50 cents per vine	$18,900,644	
Estimated 10 per cent reduction in value		$1,890,000
Cost of treatment		200,000

GRAPE LEAF HOPPER (*Typhlocyba comes*).

Total number vines in the United States	182,333,064	
Value, at 50 cents per vine	$91,166,532	
Estimated 2½ per cent reduction in value		$2,279,163

Practically no treatment is given.

MISCELLANEOUS GRAPE INSECTS (ROSE BUG, BERRY MOTH, CATERPILLARS, ETC.).

Estimated annual injury, and cost of treatment for these several species	$1,000,000
Total for grape insects	8,769,905

THE PLUM CURCULIO.

The plum curculio is a native species and from earliest times has depredated upon stone fruits, and during the past fifteen or twenty years its injuries have become very important. This insect is confined to America so far as is known, and in the United States does not occur west of about the one hundredth meridian. Taking into account its distribution and its injuries to the apple crop in the Middle West and eastern States, on the basis of a 10 per cent reduction in yield, there results a loss of about $3,250,000. Assuming a loss to the peach crop of 33 per cent, the injuries to peaches, including the cost of remedial work, brings about a loss of somewhat more than $4,000,000. On the basis of a 50 per cent reduction in yield of plums and prunes throughout the infested territory, including the cost of treatments, there is a loss of about $1,250,000.

The total annual loss to its several food plants amounts to about $8,500,000.

DAMAGES BY PLUM CURCULIO.

(*Conotrachelus nenuphar.*)

APPLE.

[The figures for the apple crop in the following estimate were furnished by the American Agriculturalist.]

Average crop, 1897 to 1907, in the infested territory (barrels)	34,292,700
Estimated shrinkage of first-class fruit, 10 per cent	3,429,270
Value, at $1.25 per barrel	$4,286,587
Value of fruit as culls, at 30 cents per barrel	1,028,781
Total	$3,257,806

On apples this insect receives but little if any treatment aside from that given in codling-moth treatments.

PEACH.

There are no available figures on the yield of peaches. It was thus necessary to determine this as accurately as possible on the basis of the number of trees and a conservative yield which each should give.

Number of trees in infested territory	90,931,542
Assuming that one-fourth bear every year, producing an average of 1 crate per tree, valued at 50 cents, net value	$11,366,443
Estimated annual loss of 33 per cent	$3,788,814
